CHEMISTS (Principal Scientific Officer grade) at a Ministry of Supply research and development establishment near London—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.640/51A.

CHEMIST (Ref. K2) to look after certain aspects of field trials work and to carry out research connected with it, two SCIENTISTS (Ref. K5–K6) to assist in planning of field trials, preparation of reports, and interpretation of data; some knowledge of mathematics required, and a MATHEMATICIAN (Ref. K7) to carry out statistical analysis, experience in probit analysis preferred, for a Research and Field Testing programme of the Defence Research Board—The Chief Superintendent, Suffield Experimental Station, Ralston, Alberta, Canada, quoting the appropriate Ref. No.

CHIEF TECHNICAL ENGINEER to take charge of an engineering section responsible for all the major calculations involved in the design and construction of factories for producing fissile material—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs.

CIVIL ENGINEERS, SANITARY ENGINEERS and STRUCTURAL ENGINEERS in a number of Departments in England and Scotland—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting 3405.LA (December 31).

DEMONSTRATOR IN PHARMACEUTICS—The Registrar, The University, Nottingham.

DEPUTY CHIEF ENGINEER for the Central Electrification Scheme in Cyprus—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.28858.B.

MATHEMATICIAN (with Ph.D. degree in mathematics, or equivalent), to be responsible for mathematical research of a semi-theoretical nature and to act as a consultant to members of a research group—The Director of Research Personnel, Defence Research Board, Department of National Defence, 'A' Building, Ottawa, Canada, quoting No. II-12.

PHYSICIST or PHYSICAL CHEMIST for work on fundamental problems associated with the hardening of Portland cement—The Cement and Concrete Association, 52 Grosvenor Gardens, London, S.W.1.

PROFESSOR AND HEAD OF THE DEPARTMENT OF ELECTRICAL ENGINEERING (Heavy), Indian Institute of Technology, Kharagpur, B.N.Ry., India—The Ministry of Labour and National Service, Technical and Scientific Register (A.8.12), York House, Kingsway, London, W.C.2, quoting A.12/UNE/150/51.

SENIOR SCIENTIFIC OFFICERS and SCIENTIFIC OFFICERS (posts are in various Government Departments covering a wide range of scientific research and development in most of the major fields of fundamental and applied science)—The Secretary, Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting No. 3599.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

General Register Office. Studies on Medical and Population Subjects, No. 4: Hospital Morbidity Statistics, a Preliminary Study of In-Patient Discharges. By Dr. Donald Mackay. Pp. 114. (London: H.M. Stationery Office, 1951.) 3s. net. [197

Memoirs of the Geological Survey of Great Britain. The Mesozoic Ironstones of England: The Northampton Sand Ironstone; Stratigraphy, Structure and Reserves. By Dr. S. H. Hollingworth and Dr. J. H. Taylor, with contributions by Dr. W. D. Evans, G. A. Kellaway, Dr. F. B. A. Welch, Dr. Vernon Wilson and Dr. A. W. Woodland. Pp. viii+211+6 plates. (London: H.M. Stationery Office, 1951.) 17s. 6d. net. [237

Annual Report of the British Welding Research Association, 1950–51. Pp. 40. (London: British Welding Research Association, 1951.) [247

British Standard 1715: 1951, Methods for the Analysis of Soaps. Pp. 42. (London: British Standards Institution, 1951.) 5s. net. [247

Philosophical Transactions of the Royal Society of London. Series A: Mathematical and Physical Sciences. No. 869, Vol. 243: On the Geometry of Numbers of Non-Convex Star-Regions with Hexagonal Symmetry. By R. P. Bambah. Pp. 431–462. 7s. 6d. No. 870, Vol. 243 A Study of the Reactions that lead to 'knock' in the Spark-Ignition Engine. By D. Downs, A. D. Walsh and R. W. Wheeler. Pp. 463–524. 17s. (London: Cambridge University Press, 1951.) [247

Forestry Commission. Britain's Forests—Cannock Chase. Pp. 16. 9d. net. Guide to the National Pinetum and Forest Plots at Bedgebury. Pp. iv+66+8 plates. 2s. 6d. net. Thirty-first Annual Report of the Forestry Commissioners for the Year ending September 30th, 1950. Pp. 75. 2s. 6d. net. (London: H.M. Stationery Office, 1951.) [247

Fitzwilliam Museum, Cambridge. Annual Report for the Year ending 31 December 1950. Pp. 10+4 plates. Friends of the Fitzwilliam Museum. Forty-second Annual Report for the Year 1950. Pp. 8. (Cambridge: Fitzwilliam Museum, 1951.) [247

Report of the Second Conference of Industrial Research Directors and Managers: the Planning and Financial Control of Industrial Research. Organized by the F.B.I. Industrial Research Committee and held at Ashorne Hill, Leamington Spa, 10 to 12 November 1950. Pp. 88. (London: Federation of British Industries, 1951.) 3s. [247

Department of Scientific and Industrial Research: Technical Information and Documents Unit. A Bibliographical Survey of the Development and Use of Substitute Materials for Non-Ferrous Metals and Alloy Steels in Germany. (Report No. RMS-2.) Pp. ii+46. (London: H.M. Stationery Office, 1951.) 1s. 6d. net. [257

Scottish Seaweed Research Association. Annual Report for 1950. Pp. 36. (Inveresk: Institute of Seaweed Research, 1951.) [257

FUTURE OF PARASITOLOGY

IN the early part of the present century, and to some extent, no doubt, earlier than this, the minds of zoologists, influenced by the rapid growth of those promising infants, biochemistry and biophysics, ceased to find inspiration in the great investigations of animal structure which are the glory of an earlier biology, and transferred their energies to physiological and experimental work. The science of experimental zoology was born and after a period of adolescence during which, with pardonable pride, it seemed to believe that morphology was no longer worth serious effort, it settled down to change the trend of biological research and incidentally to bring back, not the old morphology, but new conceptions of structure required, at different levels, by experimental study.

By the same process, by a shift from the static to the dynamic, from architecture to physiology, the outlook of parasitology is also being changed. The germ of this change was latent in the work of some of the older parasitologists who sought, but inevitably in vain, concepts and techniques which could only be found when biochemistry and biophysics were mature enough to make them available. But the new and powerful techniques were vigorously taken up for the study of parasites, and for some time now, in the pages of *Parasitology* and in those also of journals not specifically devoted to the study of parasitic life, a growing volume of experimental work upon parasites has been printed. It is not surprising, therefore, that a need has arisen for a journal devoted entirely to work of this kind. The new quarterly *Experimental Parasitology* (Acad. Press, Inc., 125 East 23rd St., New York), the first issue of which is to appear shortly, will help, by concentrating experimental work on parasitic organisms in one journal, to bring this kind of work to the attention of all biologists.

The scope and outlook of the physiological, experimental and immunological work now being done on parasitic organisms cannot be properly discussed in the space available here. Its literature is already voluminous and takes us back to surprisingly early dates. An idea of its quality, and of the fundamental problems that it raises, can be obtained from summaries of various aspects of it that have recently appeared. Thus Hobson[1] and Read[2] are concerned with our growing knowledge of the physiology of nematodes parasitic in the alimentary canals of their hosts, and their summaries show that the experimental study of these organisms is extending our knowledge, not only of the nematodes, but also of the biochemistry of the alimentary canal. Smyth[3] and Wardle[4] review what we know of those tapeworms the physiology of which has been investigated. Lwoff, and the distinguished contributors to the book[5] which he is editing, deal with the physiology of both parasitic and non-parasitic Protozoa, and thus enable us to make those direct comparisons between the biology of closely related free-living and parasitic organisms which throw so much light on the basic phenomena of life. Smyth, in common with the protozoologists, has, thanks to his own remarkable success in cultivating a tapeworm, had the advantage of study of a parasitic animal *in vitro*. As Read[5] and Lapage[6,7] have pointed out, the cultivation of a parasitic nematode in a sterile medium, when this becomes possible, will quickly increase our knowledge of these *remarkably adaptive* organisms. A technique for the experimental study of them free from bacteria is urgently required and, when it is available, we may expect not only better knowledge of nematode physiology but also valuable additions to general biology. In addition to work on helminths and Protozoa, there is, as every biologist knows, a great deal of similar work on the parasitic arthropods. Of fundamental importance also is the growth of modern *contributions to the immunology* of parasitic infestations, the study of which is making such rapid progress nowadays.

All this work, in one degree or another, fulfils the biological maxim that the animal cannot be properly studied apart from its environment. The protozoan in the blood, the helminth in the gut, the scab-mite in the skin, are all animals inseparable from those tissues of the host which they normally inhabit. The central problem, therefore, *is the relationship* of the parasite to its host. To the study of this, by one method or another, parasitology directs its energies. Important to it, without any doubt, are studies of those morphological and adaptational beauties of the parasite which still, we may congratulate ourselves, excite the interest and admiration of minds that are sensitive to them. Based also on the study of the host-parasite relationship is the economic work, the efficiency of which has gained so much from the modern outlook. We need not fear that, if we ask the parasitologist to be primarily a biologist, trained in biochemistry and biophysics, we shall lose, or delay, economic gains for which we hope. The greatest advances in our control of harmful parasites have come from the biological study of their activities. It is only common sense to believe that, when we know how the parasite breathes, feeds, excretes and uses, within its host and at its host's expense, whatever biochemical processes link it to that host, we may learn to control it, not by our present-day expensive use of dangerous drugs discovered rather by chance than by rational methods, but by attacks on one or other of the essential physiological links between the parasite and its host—a method which may turn out to be cheaper and much more effective.

This understanding of parasitic life, when we achieve it, will bring us, however, more than effective means of control. It will bring understanding of much more than parasitism. In the food canal, in muscle, liver, blood, in practically every tissue of almost every kind of animal, in the very cells of which the tissues are composed and even in their nuclei, some kind of parasite may live and wage with its host a battle that, in the course of evolution, ends frequently, *not* in the extinction of either the host or the parasite, but in a state of interdependence of one upon the other, in a mutual tolerance that may be scarcely distinguishable from the condition that we recognize as symbiosis. This conflict is based on physiology; its weapons are enzymes, ions, catalysts, antibodies. All the concepts of biochemistry and biophysics figure in its armouries. The study of it will, therefore, bring us wider knowledge of the basic processes of biology. It *is not too* much to hope that, when we understand, for example, the methods by which the nematode succeeds in living in environments so widely different as the sands of the seashore and the contents of the duodenum of a man or a ruminant, we may have uncovered much that is new to biology. It is not too much to hope that, when we understand the biology of the viruses, we *shall* have come nearer to understanding the origin of life upon earth. Meanwhile, if we are not dull, we shall, without doubt, have learnt how man may live in harmony with his own parasites.

The study of parasitic organisms, thus broadly conceived, becomes not merely the study of organisms that do harm to man and to the animals and plants that minister to human needs, with the limited aim of destroying these organisms so that man may prosper; but rather the biological study of a certain way of living, *of one of the ways in which living things* have come in the course of evolution to live together, of the value and interest of this way of living considered as an evolutionary device and of the basic problems that it puts to biology. It becomes the business of the biologist, and it is to biology that we must look for relief from the suffering, death and economic loss that parasitic animals cause.

If this is so, and if we wish this kind of work to be done, we *must make it possible for the young* biologist to do it. We need not try to persuade anybody to take up work of this kind. Men persuaded cannot do what men inspired will naturally do. There are, we must frankly recognize, young biologists who avoid the parasite because they have a horror of disease; there are others who are not 'amused' by parasitic life; there are others still who have worthier reasons for their interest in different fields; *but for those who are naturally attracted* to experimental work on parasitic organisms, are we doing all that could be done?

The problems posed by this kind of work are intricate and difficult. They cannot be made the shuttlecocks of scientific politics. They cannot be solved in the two or three years required for the acquisition of doctorates. They require a vocational drive that must have freedom for a period of years, years that will bring (unless there be lucky chance discoveries) failures, delays, disappointed hopes, years that will test to the utmost the staunchest scientific spirit.

If we ask young men and women to face such a prospect as this, we must not trade upon thei devotion to its joys and disciplines. We must give them *honour, freedom, financial security*—all the rewards that the quality and value of their wor demand. In return they will bring us, in terms o fundamental biological discovery, a recompense tha will be very great. In terms of relief of human and animal distress and suffering, the recompense will scarcely be measurable.

ADVANCES IN MEDICINE

Annual Review of Medicine

Windsor C. Cutting (editor), Henry W. Newman (associate editor). Vol. 2. Pp. x+485. (Stanford, Calif.: Annual Reviews, Inc., 1951.) 6 dollars.

In this publication, twenty-six contributors under the editorship of Cutting and Newman review the advances made during the past two or three years in a wide variety of medical topics. There are nineteen sections in the book, the last being an annotated list of such review articles as appeared in the major medical journals during 1950.

The several authors show a considerable diversity of approaches in the presentation of their subjects, and not all are equally successful in securing clarity. The opening chapter, by Burnet, on virus and rickettsial diseases, is an excellent beginning to the book. It is at once readable, informative and well but not excessively documented—there are 136 references in twenty pages of text. Attention has been chiefly confined to advances significant for clinical medicine and public health, and the subjects discussed include the use of antibiotics in rickettsial and virus diseases, recent work on poliomyelitis, influenza, rubella in pregnancy, *Q*-fever, and the Coxsackie viruses.

Grimson and Howe, who review gastro-intestinal tract diseases, approach the subject from a surgeon's point of view. The presentation is far from lucid, however, and apart from the encouraging results attributed to Banthine (β-diethylaminoethylxanthene-9-carboxylate-methobromide) in disorders ranging from peptic ulcer, œsophageal stricture and hiatus hernia to diverticulitis, ulcerative colitis and pancreatitis, there is little major progress recorded.

Diseases of the cardiovascular system are reviewed by Page and Corcoran, and this section is one of the most disappointing in the book. It certainly contains a host of recent references—338 in thirty-one pages of text—but the text to these references is extremely brief and frequently quite uninformative. The authors have assumed a knowledge of cardiovascular research on the part of the reader which few general physicians are likely to possess, and this chapter is consequently far too concentrated and technical for any but a specialist in cardiovascular diseases in search of references. Nesbit and Lapides provide a reasonable and readable evaluation of reports on tuberculosis and other infections of the urinary system, nephrolithiasis and neoplasms of kidney and bladder. An excellent and well-balanced review of the coagulation problem and hæmorrhagic diatheses and disorders of leucocytes is contributed by Finch. The general physician may perhaps feel that this section, too, is somewhat over-documented and technical, but the field covered is small and the references come in a logical sequence. Meiklejohn and Passmore confine their attention, among nutritional topics, to kwashiorkor, famine and ascorbic acid metabolism, and under the heading of allergy Rose has dealt with the relationship of the pituitary adrenal mechanism to hypersensitivity. Both these sections, and particularly the latter, are most informative and clearly written.

The chapters on the reproductive system, the nervous system, psychiatry and the respiratory system are adequate reviews which the authors wisely confine to a few specific topics in each of the fields. The traumatic effects of stress and physical agents are well discussed by Behnke. Garland's section on radiology contains much interesting material but is marred by the fault, common to so many contributors in this work, of quoting too wide a bibliography with the minimum of textual reference. In a chapter on laboratory aids to diagnosis and therapy, Peters reviews only topics in which his own experience has been considerable. They include much research on serum content of precipitable iodine, lipids and proteins, measurement of body-fluid volumes and renal clearances. Scholtz and Williamson stress the growing appreciation of the close relation between skin disease and internal medicine and review progress in fields where this relationship is conspicuous.

Selye contributes an essay on the general adaptation syndrome which provides an admirable summary of his own work and views on this subject. He does not attempt to cover all recent work in this field, and the twenty-two references are all to the author's own publications. Aub and Nathanson summarize the clinical and experimental work done with adrenotropic hormone and cortisone in neoplastic conditions and conclude that these drugs affect the environment of the tumour rather than the growth itself. Kuzell has limited his contribution on diseases of bones and joints to rheumatoid arthritis and gout, and his review of the work on these subjects is most valuable. There is a full discussion of the use of adrenotropic hormone and cortisone in these diseases.

The content of this book may be summarized as a laudable attempt to perform an impossible task.

JACOBSON'S ORGAN

Ouvrages sur l'organe voméro-nasal

Par Louis Jacobson. Avec préface et notes par O. C. Hollnagel-Jensen et Dr. Erik Andreassen. Pp. xxxi+175. (Copenhague: Einar Munksgaard, 1948.) 30 kr.

Louis Levin Jacobson, having so far escaped the inquisitive attentions of the denigrator, enjoys the unusual distinction of having actually discovered the vomeronasal sense organ of vertebrates with which his name is associated. Its duct, however, the nasopalatine canal or Stensen's foramen incisivum (canalis incisivus), had been seen by Vesalius in the dog and horse, and, apparently, in its vestigial state, in man himself. This Vesalian observation, which is described on p. 54 of the 1543 "Fabrica" and on p. 67 of the 1555 edition, is not correctly quoted in Cuvier's report reprinted in the present volume. Jacobson's organ in its most highly developed condition, as exemplified in some reptiles[1], is in communication with the nasal cavity, and secondarily also with the buccal cavity by the incisive or nasopalatine canal. Jacobson was the first to establish the latter connexion. The organ itself is represented in the early human fœtus, but later it becomes vestigial, and may be absent in the adult. Jacobson's discovery was first made known by Cuvier in 1811[2] during Jacobson's life-time.

This exhaustive and beautifully produced work by Hollnagel-Jensen and Andreasen, printed in an edition of three hundred numbered copies, includes the following eight sections: (1) Portrait of Jacobson. Preface of 20 pp. describing the main events of his life, and bibliographical details of his unpublished MSS. which the authors succeeded in finding. Apart from the discovery of the vomeronasal organ Jacobson's most important contribution to the literature of comparative anatomy was the demonstration of the existence of a second portal vascular system, the renal portal system, in all classes of vertebrates except mammals. The authors dispose of the claims on behalf of Ruysch and v. Soemmerring to have anticipated Jacobson in the discovery of the vomeronasal sense organ. We learn that Jacobson was not eligible for a chair in the University of Copenhagen in 1815 on the ground that he was "un homme adhérant à la religion mosaïque". (2) French translation of 22 pp. of an undated MS., with notes, presented to the Academy of Science of Denmark on January 4, 1811, which contains a description of a secretory organ in the nose hitherto unrecorded. Three figures are mentioned in the MS. but were not found by the senior author when the text was discovered. The Academy did not publish the paper, which opens with the well-known and impeccable quotation from the Latin edition of Galen—"Quicunque vult operum naturæ esse contemplator, non oportet eum anatomicis libris credere, sed propriis oculis". (3) The only description of the vomeronasal organ published by Jacobson himself was a paper in Danish printed in a Copenhagen veterinary journal in 1813. This paper is not recorded in bibliographies and is practically unknown. In it Jacobson states that he had already sent to the Denmark Academy of Science a complete description of the organ which was not published, but which he now uses and supplements as the basis of the article in the veterinary journal. This paper is also translated into French in 19 pp. of the present work, and its two plates of the horse are reproduced. The animals mainly dealt with are the ox, horse, pig and dog. (4) When Jacobson was in Paris in 1812 he deposited with the Institute of France a memoir on his discovery entitled "Description anatomique d'un organe observé dans les mammifères", which was read on January 13 of that year but not printed. The text of this MS. was recovered by our authors in 1946, but the 12 plates by which it was illustrated could not be found. This was the MS. used by Cuvier in drafting his report of "1811". It is now published in full in 17 pp. (5) Reprint of 8 pp. of Cuvier's report on the preceding MS. dated March 2, 1812, with a collotype reproduction of the first page. The report itself was published contemporaneously in the Annales du Muséum d'Histoire Naturelle, XVIII, "1811". (6) Collotype reproduction of 57 pp. of the whole of the most important MS. which was recovered by the senior author and is described in section 2. (7) Preserved in the archives of the Veterinary Society of Denmark is a packet of unpublished figures inscribed "Jacobson's drawings for his researches on Jacobson's organ". They are apparently not all by Jacobson himself, and the authors reproduce on 25 pp. those which have a particular bearing on the subject. The animals included are monkey, cat, dog, otter, hedgehog, rat, rabbit, hare, little anteater, pig, deer, sheep, ox, musk-deer and horse. (8) Notes and commentary.

Such are the contents of this important and conclusive work. It is no exaggeration to claim that on the subject of which it treats there is no more to be said. The senior author died in 1946. It is to be hoped that the junior author, Dr. Andreasen, will pursue his historical studies on Jacobson, and let us have another memoir of the same class on Jacobson's classic researches on the renal portal system. It is a remunerative subject and needs clarification.

[2] So dated, but Cuvier's report was not completed until March 1812.

HUMANISM AND TECHNOLOGY

Man the Maker

A History of Technology and Engineering. By R. J. Forbes. (The Life of Science Library.) Pp. xv+355+41 plates. (London: Constable and Co., Ltd., 1950.) 25*s*. net.

This volume is a recent addition to the Life of Science Library and maintains the established tradition of the series by its treatment of the history of technology in relation to its human setting. In his preface, the author claims that in the combined experiments and technical creations of hundreds of generations the figure of humanity rises as clearly in this field as in the fields of literature and art. He continues, "In order to make this clear and to show how deeply such mechanical arts as engineering and technology are embedded in the spiritual life of mankind, we have followed up a few threads of this history from the dawn of human life to the dawn of the Atomic Age. . . . In keeping with the general design of the 'Life of Science Library' we have accordingly restricted ourselves to the story of such essential topics as power resources, transportation and communication, metallurgy, textiles, glass, chemical technology, and some aspects of civil engineering."

The first chapter, "Man and Nature", is important as an introduction to what follows. It is concerned with man's relation to Nature, the difference between discovery and invention, and the widespread diffusion of certain inventions. In the main, the first half of the book is arranged chronologically so that successive chapters deal with "The Dawn of History", "The Great Empires of the Ancient Near East", "Greeks and Romans", "Wardens of the Classical Heritage". The last-named refers to the important part played by the Arabs. The next chapter, "Technology and Theology", covers roughly the same period and describes many developments which paved the way for the birth of the 'New Science' treated in Chapter 7 under the title "New Wine into Old Bottles (1500–1750)". The three remaining chapters relate to steam, the conquest of distance, and steel and electricity. The first is closely associated with the Industrial Revolution and the perfecting of steam power; the new iron metallurgy, textile factories and the rise of a chemical industry are treated in some detail. In Chapter 9 the development of road building, bridges, canals, means of transport on land, sea and in the air, all make interesting reading, and, with modern applications of electricity described in the last chapter of the book, a fitting climax is reached in the story of man's achievement. The epilogue—"Technology and Progress"—though brief is apt. The limitations of science are recognized, the essential unity of mankind is stressed and the author concludes: "No world can be built on the basis of material progress alone. We must supplement our material gains with a deeper understanding of the mind and spirit. Using the science of matter to implement the science of man is the task of present and future generations."

The numerous plates and illustrations, together with a good bibliography, add to the value of this informative and readable book.

H. D. Anthony

PREHISTORIC METALLURGY OF COPPER AND BRONZE

Notes on the Prehistoric Metallurgy of Copper and Bronze in the Old World

By H. H. Coghlan. (Pitt Rivers Museum, University of Oxford. Occasional Papers on Technology, 4.) Pp. 131+16 plates. (Oxford: Pitt Rivers Museum, 1951.) 15s.

Though doubtless the last word has not been said on the prehistoric metallurgy of copper and bronze in the Old World, this work by H. H. Coghlan is certainly the most important treatise on the problem that has been published for many a long day. In the Tripos examination at the University of Cambridge the question, "Starting with the appropriate ores, how would Bronze Age man proceed to fashion a palstave?" has once or twice appeared; I venture to think that few of our older archæologists would have been able to obtain an 'alpha plus' on this question, which yet is fundamental to the subject. However, the publication of this book now renders any excuse untenable.

What makes the book authoritative is the fact that Mr. Coghlan had had years of metallurgical experience before he became curator of the Newbury Museum. It is thus written by a man who has knowledge, not by an archæologist who has merely read about smelting. The work opens with chapters on native copper and non-ferrous ores and their discovery in antiquity. Chapter 3 deals with the sequence of the metals and the results of analysis. There follow chapters on the mechanical properties of copper and bronze and the different methods of casting. An important chapter describes the various implements known to have been used by the prehistoric metallurgist, such as tongs, drills, files, etc. Later in the book the methods of soldering and welding are outlined. The work concludes with several chapters on the results of metallurgical examinations of a number of ancient examples of the metal-worker's art.

Mr. Coghlan does not think it possible that Bronze Age man could have obtained his copper from the abundant copper sulphide ores. Here one may perhaps hesitate to agree. Bronze Age man was a skilled metallurgist. Everything seems to point to the fact that he was perfectly aware of what he was doing. It was not all mere chance. The speed with which the knowledge spread that copper with 10 per cent tin and without other ingredients was the most suitable alloy is impressive. It argues that the development of metal-working took place in a limited geographical area, that the men themselves were consciously experimenting and that they knew what they were trying to do. Sulphide ores require the prior process of roasting before reduction; but the abundance of these ores would surely have interested the Bronze Age metal workers, and they were quite capable of finding out how to utilize them to obtain the needed pure copper.

M. C. Burkitt

BRITISH VARIETIES OF CEREALS

Cereal Varieties in Great Britain

By R. A. Peachey. Pp. 202. (London: Crosby Lockwood and Son, Ltd., 1951.) 21s. net.

During the past fifty years there has been an endless interest in the subject of cereal varieties, largely due to the increased demand for agricultural produce of definite quality for specific purposes, such as is required in the processes of baking and malting. With the great increase in agricultural production in Great Britain and indeed throughout the world since 1939, the interest in cereals has been accentuated still more. This is partly due to differences in their yielding capacity; but recent advances in the mechanization of harvest operations have shown the greater suitability of some varieties of cereals to the changes required by this development. In "Cereal Varieties in Great Britain", the author has brought together in a most available manner the information of a general nature regarding the principal varieties of wheat, oats and barley in cultivation throughout this country.

This book is in reality a photographic record of the varieties of cereals grown in Great Britain at the present time. It is obvious on looking at the illustrations that each specimen ear has been selected with great care to show so far as possible the distinguishing botanical features of each variety. On the whole the illustrations are very faithful to the living specimens. The book illustrates and describes sixty-seven varieties of wheat, sixty-one varieties of oats and eighteen varieties of barley—that is to say, nearly all the varieties which could possibly be found growing as field-crops in the British Isles. The selection of the varieties is on a wide scale and not confined to those varieties the superiority of which in some or other direction has been demonstrated by authoritative field trials and qualitative determinations.

Particular attention has been paid to the origin of a variety. Wherever possible the parentage of the variety, and the breeder or introducer, as well as the date of introduction into commerce, are given.

The book is of outstanding importance to all concerned with the cultivation and identification of cereals. With the aid of the descriptions of the young plant, ear, glume, grain and straw and the series of exceptionally good illustrations, the identification of any unknown cereal should offer few difficulties. Methods of harvesting and the factors which are important in considering the suitability of varieties to certain conditions of soil, climate, etc., are also dealt with. This part should appeal to the practical man. Seedsmen and crop inspectors especially will find it a most useful guide and reference book.

J. S. L. Waldie

The Heaviside Centenary Volume

Pp. v+98+6 plates. (London: Institution of Electrical Engineers, 1950.) 10*s.*; 4*s.* to members.

THIS well-produced and attractive volume is a record of the special meeting of the Institution of Electrical Engineers, held on May 18, 1950, to commemorate the centenary of the birth of Oliver Heaviside (see *Nature*, 165, 991; 1950). It contains the texts of the tributes paid to his memory by Prof. E. B. Moullin, president of the Institution, Sir Robert Robinson, president of the Royal Society, Sir Edward Appleton, Dr. M. J. H. Ponte, representing the Société Française des Électriciens and also the Société des Radioélectriciens, Sir Archibald Gill, Dr. O. E. Buckley, president of the Bell Telephone Laboratories, Prof. Harold Jeffreys, Sir Edmund Whittaker and Dr. G. F. C. Searle.

In addition, there are the following papers: "Oliver Heaviside—The Man", by Sir George Lee; "Some Unpublished Notes of Oliver Heaviside", by H. J. Josephs; "An Appreciation of Heaviside's Contribution to Electromagnetic Theory", by Prof. Willis Jackson; "Heaviside's Operational Calculus", by Prof. Balth van der Pol; "Fifty Years' Development in Telephone and Telegraph Transmission in relation to the Work of Heaviside", by Dr. W. G. Radley; "Heaviside's Pure Mathematics", by Prof. Harold Jeffreys; and "Oliver Heaviside—A Personal Sketch", by Dr. G. F. C. Searle. These papers bring to light many facts about Heaviside's character and his work which had been obscured by the seclusion in which he lived and by the mode of presentation and inherent difficulty of many of his published papers. The most important section of the book is the impressive reconstruction by Mr. Josephs of portions of Heaviside's unpublished work under the following five headings: infinite integrals, 'physical' mathematics, electric circuit theory, electromagnetic theory and unified field theory. It is to be hoped that the contents of other portions of the manuscripts now in the possession of the Institution will also be published in due course.

The Institution of Electrical Engineers is to be congratulated on the preparation of a magnificent tribute to one of the most famous of its honorary members and to the man whom it selected to be the first recipient of the Faraday Medal.

The World of Science

By Dr. F. Sherwood Taylor. Second edition. Pp. xviii+1064+48 plates. (London: William Heinemann, Ltd., 1950.) 21*s.* net.

THIS encyclopædic volume can be confidently recommended to the man of science and layman alike, both for general reading and as a reference book. I have found the first edition, published in 1936, to be a most valuable source book and its index a reliable guide. This second edition should prove equally valuable and interesting reading, for it is, in fact, largely a reprint of the first (bearing the same page numbers), but with a number of pages inserted at various points to carry the new material. Most of the remarkable advances that have been made since the first edition are covered; they include atomic energy, radar, gas turbines, new elements, recent astronomical theories, new drugs, and modern theories of the origin of man.

The printing, especially the line blocks, is not as sharp as it might be, doubtless owing to the method of reproduction from the first edition which has been employed. On the other hand, this slight shortcoming is offset by the remarkably low price of 21*s.* for these days (which might be compared with the 8*s.* 6*d.* for the first edition which had almost the same number of pages).

The last chapter "Looking Ahead" differs only by the addition of a sentence or two from that written fourteen years ago; surely the author's publishers will encourage him before an equally long period passes to produce a third edition which will not have to be so closely tied to the original text. H. R. LANG

Mechanics

A Text-Book for Engineers. By James E. Boyd and Prof. Percy W. Ott. Third edition. Pp. xii+422. (London: McGraw-Hill Publishing Co., Ltd., 1950.) 38*s.* 6*d.*

IT is always a pleasure in welcoming a book which bears the stamp of thoroughness, and this book is an example of a carefully thought-out plan to put clearly before students the fundamentals of the subject. The execution of this plan has resulted in a really sound book, now in an enlarged third edition, which cannot fail to assist the student. The aim is to emphasize with illustrative examples the fundamental principles, and to encourage the student to use logical thinking and suitable mathematical methods in solving problems based on the principles. Greater stress is placed on the application of the principles to problems, especially numerical ones, rather than on the mathematical derivation of the principles or the relationships which they bear to one another.

The authors have evidently spared no time or trouble in an endeavour to make things clear, and they have eminently succeeded. The short space devoted to the principle of virtual work gives the clearest exposition of this very useful method seen by the reviewer in a book of this standard. The same thoroughness which pervades the text is repeated in the diagrams, which are excellently done.

Progress in Biophysics and Biophysical Chemistry

Editors: Dr. J. A. V. Butler and Prof. J. T. Randall. (Progress Series.) Pp. viii+279. (London: Butterworth-Springer, Ltd.; New York: Academic Press, Inc., 1950.) 50*s.*

THIS book is the first of a new series which will present at intervals review articles of selected topics in biophysical research. Biophysics is a borderline subject which is difficult to define precisely. Interest in recent years has perhaps centred more on the structure of cells and tissues than on the physics of the mode of operation of organs. However, the nine contributions to this first volume have been well chosen and cover a wide field.

The reviews are in general well documented and provide a useful starting-point for further reading. They are written in a critical vein and give expression to the opinions of the various authors. They combine, therefore, the personal interest of an essay with the substance of a progress report. The aspects covered include the properties of solutions of large molecules, fundamental molecular structures in biological systems, X-ray and light scattering by protein solutions, bioelectric potentials, phase-contrast microscopy, the theory of local refractometry, the assay of biological materials by soft X-ray absorption, the tolerance of man for radioactive isotopes and the mechanical properties of muscles and fibres.

The production of the book is of a high standard.

D. P. RILEY

NATURAL AND ARTIFICIAL PRODUCTION OF ATMOSPHERIC PRECIPITATION

A DISCUSSION on the "Natural and Artificial Production of Atmospheric Precipitation" was held on August 10 at Edinburgh as part of the programme of Section A (Mathematics and Physics) of the British Association. The session was opened by the president of the Association, H.R.H. the Duke of Edinburgh.

B. J. Mason (Imperial College of Science and Technology, London) read the first paper and began by describing the mechanisms responsible for the release of natural precipitation, emphasizing that an understanding of the fundamental physical processes is essential if artificial rain-making experiments are to be carried out intelligently and their results assessed in a realistic manner. He said that the collision and the resultant coalescence of droplets having differential rates of fall, while capable of producing only drizzle or light rain from layer clouds, can release a heavy shower from a deep, vigorous, cumulus cloud by initiating a water-drop chain reaction. This process will be favoured in tropical regions, particularly in unstable maritime air-masses, where sea-spray may supply the larger droplets required to start the coagulation process. In temperate latitudes and well inland, showers are more likely to be released by the action of ice crystals. Growing initially by diffusion, the crystals afterwards sweep up supercooled cloud droplets to form pellets of soft hail, which may melt to form raindrops. Rain falling from deep layer-clouds generally originates from melting snowflakes, which are formed by the coalescence of ice crystals. In cumulus clouds containing strong updraughts and high concentrations of liquid water, a water-drop chain reaction may be initiated by the shedding of large droplets from hailstones which amass supercooled water at a rate greater than it can be frozen.

In describing and assessing the results of artificial rain-making experiments, which attempt to induce precipitation by 'seeding' suitable clouds with pellets of dry ice, crystals of silver iodide or small water-droplets, Mr. Mason said that there has been a distinct tendency to draw spectacular conclusions on the basis of too few observations, and that too little attention has been paid to the need for adequate control experiments. However, many cases have been reported of rain falling from clouds a few minutes after seeding. Although in any particular case it is not possible to ascertain that this would not have happened without seeding, in many careful dry-ice experiments carried out in Australia by the Council for Scientific and Industrial Research (now the Commonwealth Scientific and Industrial Research Organization), under the direction of Dr. E. G. Bowen, rain has been observed to fall from seeded cumulus clouds, while similar clouds in the immediate vicinity produced no precipitation. Since, for a high probability of success in the dry-ice experiments, the cloud top must be colder than − 7° C. and rain is likely to fall naturally if it is colder than − 12° C., there is only a narrow range of conditions in which seeding with dry ice can anticipate natural events. The position is still more unfavourable in the case of silver iodide, which suffers the additional disadvantage that it becomes inactive as an ice nucleus when exposed to strong sunlight for about one hour. Calculations indicate that spraying small water-droplets into the base of the cloud should be a more efficient method of releasing showers from warm cumuli, and the results of recent experiments in Australia are encouraging.

The introduction of dry ice into supercooled layer clouds tends to produce 'over-seeding' and therefore to inhibit precipitation. This danger is reduced by the dissemination of silver iodide from the ground; this method is being used extensively in the United States, but an accurate assessment of the results will be possible only after extended trials in many different regions, comparing the precipitation on a statistical basis with that produced naturally in corresponding control areas. Generally layer clouds will produce little precipitation unless they possess considerable depth, in which case their tops may often be sufficiently cold for precipitation to be released naturally.

Mr. Mason said that there is little doubt that precipitation may be released by seeding techniques. The important questions are how much can be so released which would not fall naturally, and whether the time of release and hence its distribution can be altered. It is possible that, by seeding, the onset of precipitation from a growing cumulus may be advanced by a few minutes, and from frontal cloud systems by perhaps a few hours. This might be of importance in increasing the rainfall in a given area; but judging the optimum time for seeding would, in most cases, be very difficult. It seems unlikely that the rainfall pattern over large areas can be altered materially by cloud seeding, although local modifications may be effected.

It was suggested by Mr. Mason that perhaps the greatest value of rain-making experiments is to be found in the impetus they have given to fundamental research in the physics of clouds and precipitation; they should be continued as scientific experiments in close collaboration with theoretical and laboratory work on the fundamental physical problems, for only in this way can their potential economic value be satisfactorily assessed.

F. H. Ludlam (Imperial College of Science and Technology, London) emphasized that the time-scale of precipitation processes is controlled mainly by the macroscopic features of cloud development, and showed by time-lapse photographs of cumulus clouds that the life-history of a particular mass of cloudy air may be completed in a few minutes. He went on to discuss quantitatively the formation of raindrops and hailstones in shower clouds, tracing the growth of these elements by coagulation in relation to the elapsed time and their height above the cloud base. His calculations show that a droplet of sea-spray of radius about 30μ is capable of releasing a shower via a water-drop chain reaction in a warm cumulus cloud having a strong updraught; alternatively, this process can be started by a wet hailstone in the manner described by Mr. Mason.

It was Mr. Ludlam's opinion that, even in temperate latitudes, rain is released from shower clouds without the aid of ice crystals; but more critical observations are needed. He also discussed the possibilities of inducing and inhibiting showers by seeding techniques, pointing out that seeding can be used as a tracer in studying the further development of a cloud. For this reason, and also because he was more optimistic about their potential economic value than other speakers, he hoped that such experiments would be conducted on an increasing scale in the British Isles.

In a paper entitled "Radar Echoes from Precipitation", R. F. Jones (Meteorological Office) pointed out that normal radar equipments working on wavelengths of 3 or 10 cm. can, at ranges greater than ten miles, detect only that part of the cloud in which there are either raindrops, ice crystals exceeding 1·5 mm. diameter, aggregates of ice crystals or ice crystals with a wet surface. He described some results obtained with the radar equipment at East Hill (near Dunstable) which has both position-plan indicators and range-height indicators to give a three-dimensional picture of the echoes received from precipitating clouds. Different weather types are associated with markedly different radar responses, a fact which was clearly illustrated by photographs of the echoes obtained from cloud systems associated with a warm front, a cold front and an occlusion, all of which were of very different character from those obtained from shower clouds. The echoes from layer clouds are generally of limited vertical extent and contain a narrow band of great intensity (the 'bright band'), while those from cumulo-nimbus appear as narrow vertical columns attaining heights of perhaps 40,000 ft.

Mr. Jones went on to relate the appearance of the echoes, the rate of ascent of their tops and the temperatures of their summits as measured by aircraft, to the mechanisms of precipitation release. In particular, he associated the appearance of the 'bright band' in layer clouds with the melting of snowflakes, and the echoes from cumulo-nimbus (which show no 'bright band') with the existence of large water-droplets, often supercooled, which must have formed by the coalescence process. He reported on some aircraft observations which appear to support these interpretations.

In a paper read by H. P. Palmer, Dr. A. W. Brewer (Oxford) stated that in Great Britain nearly all rain originates from ice crystals, and because of this it is a reliable rule in weather forecasting that cumulus clouds will not give showers until the temperature of their summits falls below − 10° C. As first suggested by Bergeron, an ice crystal will grow rapidly in a supercooled water cloud; but it is important to consider the origin of these crystals. Suitable ice-forming nuclei are found in the atmosphere; but they are comparatively rare. Their concentration has been measured by Findeisen *et al.* in Prague, and also in Oxford, by the cooling of air by expansion in Wilson cloud chambers. In the relatively polluted air of these cities the ice nuclei were present in concentrations of only about 1 per m.^{3} at − 10° C. Dr. Brewer suggested that ice crystals must multiply during their growth by sublimation since it is not until much lower temperatures than − 10° C. are reached that the ice-forming nuclei are sufficiently numerous to account for all the raindrops which are produced. He reported that ice crystals which are growing rapidly and have dendritic structures release very small splinters of ice. Thus, although only a very few ice crystals may appear originally in a supercooled cloud at − 10° C., they will grow rapidly in a form liable to fracture; several splinters may form at each fracture, and themselves act as ice nuclei. In this way, a sufficient number of ice crystals may be formed to account for the number of raindrops reaching the ground.

I. C. Browne (Cambridge) described his use of a radar set with a vertical beam and range-amplitude display to study precipitating clouds, in conjunction with observations of the mass and electrical charge of raindrops and the electric field at the ground. He has made a particular study of the variations of echo intensity with height in order to determine the mass and growth-rate of the precipitation elements. In particular, thunderstorms sometimes show a striking increase of echo intensity with decreasing height in a region beneath the freezing-level, which affords some evidence for the growth of drops by coalescence and their multiplication by a chain reaction. The observations yield a value for the updraught velocity in the chain-reaction region. In warm-front rain the echo intensity indicates that at about 1 km. above the melting-level ice crystals are growing at a rate of about 150 μgm./km. Calculation indicates that they could grow at only 50 μgm./km. by sublimation, the inference being that they were growing at about 100 μgm./km. by accretion. The observations also indicate that near the 0° C. level each snowflake, on the average, coagulates with another.

B. J. Mason

SEED PATHOLOGY*

By Dr. MARY NOBLE

Department of Agriculture for Scotland

Agricultural and Horticultural Aspects

EVEN the earliest agriculturists realized the general desirability of using good seed; but it is very surprising that to-day so little attention is paid to the presence of disease in what is otherwise regarded as 'good' seed. I refer in this respect to true seed in the botanical sense, the health of other planting-stock having been greatly improved recently owing to certification schemes covering potatoes, soft fruits, etc. This is probably because most seed-transmitted parasites do not have any immediate effect upon germination; they do not kill the seed outright but multiply upon the emerging seedling, which often then succumbs to the attack; or, as in the case of loose smut of barley, the parasite may pass most of its life-cycle as a symbiont. Such seed, if tested by orthodox methods, is classed as 'good seed' but is, in fact, responsible for considerable loss of crops not only in Great Britain but also the rest of the world. To take, as a case in point, an example from one of our most familiar crops—the turnip. Dry rot of turnip caused by *Phoma lingam* has been known for very many years; but although the farmer has known this disease as a rot of the root, the growers of swede and turnip seed only recognized it comparatively recently. Swede roots are replanted for seed-production in the second year, and it was found that the base of the shoot was often attacked by the disease known as 'canker'. The important point is that it was not until 1930 that this 'canker' was proved to be merely 'dry rot' in another form; and what was even more important, that the fungus also infects the seed heads, the pods and even the seed itself but without causing reduction in germination. Until this point was properly understood, turnip and swede seed samples were frequently severely infected by dry rot, because although the seed grower was careful to select only the finest roots for propagation he very often planted them in soil which he proved to be suitable for the purpose but which had also thereby become infected with the fungus. The disease is soil-borne as well as seed-borne, so that until recently the importance of seed-borne infection was not fully realized, and even yet it is frequently overlooked that soil infection may have arisen from seed. Some years ago observations made at East Craigs showed that as little as 2 per cent infection of the seed could lead to considerable loss of crop and that this amount of infection is still quite common.

---

* Substance of a paper read on August 13 before Section K (Botany) of the British Association meeting at Edinburgh.

This is not surprising when the method of growing the crop is considered. The seed is sown about ten times more thickly than the resulting crop and infection is disseminated throughout the field. At the time of 'thinning', the rejected plants are not removed but left lying in close proximity to those which remain, so that the risk of infection is not reduced at thinning time but multiplied tenfold. This principle applies to very many similar seed-borne diseases. Again, if seed is sown thickly to make up for low germination the risk of infection is correspondingly increased, as in this disease the fungus does not die before the seed.

Dry rot infection can be very well controlled in the seed by treatment with hot water, and in the north of England this is done as part of the National Agricultural Advisory Service. Generally, however, swede and turnip seeds are sown without any treatment, although even dusting with a mercurial fungicide greatly reduces infection; and from this disease alone the crop loss is considerable.

Again, infection sown with the seed of one crop may remain in the soil to attack a later one. For example, another brassica crop following a swede crop which had dry rot may become in turn infected. In 1948 the ubiquitous fungal parasite *Sclerotinia sclerotiorum* was found carried as a sclerotium in turnip seed. This provided the source for soil infection capable of attacking artichoke, carrot, etc. Blind seed disease of rye-grass presents quite a different case. This disease, caused by one of the Sclerotiniaceae, was not recognized in Britain until some ten years ago, although rye-grass was for a very long time the only British cultivated grass and indeed the only one of which the seed could be purchased for sowing. The causal fungus, the fructification of which arises from the seed, is very tiny and insignificant, and it is possible that this disease was present much earlier but unrecognized; on the other hand, certain changes had occurred in the rye-grass seed-growing industry which may at least have led to its increase.

One change was the concentration of seed-growing in the areas where the best pastures were found in Britain (Kent, Ayrshire, Aberdeenshire) and, overseas, in New Zealand. This arose from the fact that farmers could not be sure of getting seed of the best pasture strains anywhere else, seed certification schemes being a very recent development. It does not follow that seed production requires the same ecological conditions as pasture development, and in this case the disease is most severe where cool moist weather conditions prevail.

Another change which was more important from the seed pathology point of view was the introduction of improved, leafy strains of rye-grass in Britain as well as in New Zealand. These strains comprised much more uniform populations than the old 'commercial' strains and came into flower much more synchronously than the latter. Thus in adverse weather conditions the damage was greater. Again, these new improved strains have proved genetically to be more susceptible to the fungus and some at least are now being re-selected with reference to this factor. Trials are also in progress with growing the seed in suitable 'seed' areas as against the good pasture areas.

In horticulture the problem of seed health is studied even less than in agriculture. For example, all the sugar beet seed now sown in Britain is disinfected chiefly against the black leg organism (*Phoma betae*); but very few market gardeners treat red beet seed although it is quite as common as sugar beet.

Dwarf beans, especially of the variety 'Canadian Wonder', are often infected with halo blight, a bacterial disease, and no great effort seems to be made in Britain to avoid the disease. In New South Wales, an inspection scheme ensures the health of dwarf bean seed.

Seed Pathology and Seed Testing

The practice of seed testing or seed analysis is, of course, intimately bound up with seed pathology, and in this Great Britain has from the beginning lagged behind the Continent and the United States—at least in officially implementing the recommendations of the few who pointed the way.

Thus the first official seed-testing station in the world was established in Saxony in 1869. In 1885 a writer in the *Transactions of the Highland and Agricultural Society* pleaded that Scotland might also set up such stations, especially as the Royal Agricultural Society of England had been testing seed for its members since 1871 and had in 1882 laid down standards for purity and germination. But although a departmental committee set up to examine farm seeds had recommended in 1900 the establishment of a station, nothing was done as it was officially considered that the public would not take advantage of such facilities, or perhaps the reason given by R. H. Elliot, addressing the British Association in 1904, was more accurate: "The bewildering variety of our national affairs no doubt leaves little time for the Government to notice the needs of the biggest and most important industry of the kingdom", a reproach which is fortunately not true to day.

But seed pathology was even at this time being studied elsewhere in the world. At Iowa the work was begun by Bessey, and in 1886 a State College bulletin was issued on the results of germination tests with notes on the fungi. It is surely not without significance, considering the leading part still taken by Iowa in seed testing and seed pathology, that from the first these two studies were so closely allied in that State. Every mycologist knows the initials which represent the authorities for the fungus name *Helminthosporium sativum*, P. K. and B., but how many know that Pammel was a botanist on the staff of the Station, and that Charlotte King, at that time assistant botanist, became an official seed analyst of Iowa? Nevertheless, this fungus, so commonly seed-borne in American crops, was not named until 1910, when these authors published a bulletin on *Helminthosporium* spp. on barley, including *H. gramineum* and *sativum*, which they described as seed-borne.

For very many years the leading work in seed pathology was carried out in the United States and in Holland, where Dr. Lucie Doyer was the pathologist at the State Seed Testing Station at Wageningen, a centre which has always been noted for generously helping and co-operating with others.

In Britain very little attention indeed was paid to seed testing in relation to pathology, and this in spite of the repeated warnings even from the time of Jethro Tull: "In some sorts of seeds the goodness cannot be known by the eye". Sir John Sinclair said in 1782: "So far as oats are concerned—the clearest and best-looking oats when sown often produce the worst crop". But at last in 1920 the first and only British Seeds Act was passed, giving the farmer much greater protection and security in purchasing seeds than ever before. But even then, only certain crops were safeguarded; the Act does not apply to all seeds. Not that this was required where honest seedsmen were concerned, and there were several excellent seed firms all over the country whose names to-day still are sufficient guarantee; but there always have been less scrupulous merchants and individuals whose activities caused severe loss to farmers and gardeners.

However, even the most skilled and honest seedsman could not be blamed for selling seed carrying infection which no one knew how to detect. In many cases, indeed, it was not even known that the seed was infected at all, as has been shown in the case of dry rot of swedes. Surveys of the various seed crops would have given valuable information; but plant pathological survey work of this nature in Britain was greatly restricted because of lack of staff and facilities.

But pioneer survey work was done by Dillon, Weston and Brett on cereal seed in England, by Hickman on pea seed, when he found twenty-six out of twenty-nine English-grown samples to be infected with pod spot; the Ministry of Agriculture's Plant Pathology Laboratory continues to examine seed for export, and in Northern Ireland Prof. A. E. Muskett and his collaborators are doing valuable work. In Scotland the work begun by Mrs. Alcock, who published in 1931 an annotated list of seed-borne diseases, has been to some extent continued.

In Canada, however, such a survey began in 1937, where, to quote Craigie: "Seed-borne diseases exact a heavy annual toll from every important farm crop in this country".

As already noted, the United States and Holland were among the first countries seriously to study the problem.

The development of techniques by which these diseases could be detected is in itself a fascinating study which can only now be briefly outlined.

There are two main lines of approach: (1) to reveal the total number of seeds in any given sample which are harbouring an organism—fungal, bacterial, animal or virus, saprophytic or parasitic; (2) to assess the likelihood of specific infection giving rise to disease in the crop.

The first approach is appropriate when surveying and also when examining seed for export, and the second when examining seed for such purposes as the operation of inspection schemes where specific diseases require to be detected. With any one sample of seed the result obtained is greatly affected by the method used. In a recent paper from Canada, Wallen and Skolko state: "Standardization of seed testing methods in respect to germination and purity has been attained through the Association of Official Seed Analysts of North America and, at the international level, through the International Seed Testing Association. Much less agreement exists in the matter of testing seed for the presence of pathogenic organisms. The reason for this lack of uniformity in methods of disease diagnosis may be attributed primarily to the development by individual laboratories of seed testing methods especially suitable to their own requirements, facilities and personnel. Standardization has undoubtedly also been hampered by the fact that comparatively little is known of the seed-borne phases of many of these organisms, the failure to develop satisfactory methods of detection for seed-borne pathogens, and the emphasis on the empirical application of seed treating procedures for their control, with the consequent neglect of fundamental information as to how the seed treatment is operative. As a consequence of the differences in seed testing methods, misunderstandings are inevitable and proper interpretation of reports is not possible."

In this paper the authors were dealing with the 'Ulster', 'Ottawa' and 'New Zealand' methods—variations in the agar plate method of testing flax seed. The seed to be examined is, in the Ulster method, plated directly on to malt agar without prior surface disinfection or washing; slow-growing fungi are soon overgrown if the seed is heavily contaminated. In the Canadian method a disinfectant is used, and this makes the separation of the fungal flora easier. But in both methods the seed germinates, and in so doing may lift the infected cotyledons or even the testa above the surface of the agar. In the New Zealand method this difficulty is overcome by using deep agar and submerging the seeds, which are first washed in running water. More recently, Hagborg and Warren in Winnipeg have very ingeniously used 2,4-*D* to inhibit germination of the seed, simply adding the 2,4-*D* to the agar. Wallen and Skolko draw this very reasonable conclusion from their study: it is not the purpose of this paper to suggest which of the three methods should be adopted in seed-testing procedure but rather to indicate the necessity of defining the method on which a given report is based.

It might be further mentioned that even the disinfectant used for surface sterilizing can alter results. Thus in examining wheat seed for *Septoria nodorum* by plating, I found that 'Chloros', a chlorine type of dairy disinfectant, was less drastic in killing fungi than methylated spirit, but controlled bacterial contaminants more efficiently. This type of disinfectant has also the added advantage that the seed need not be washed again before plating—a process in which certain fungi (for example, those with pycnidospores ?) may be spread from an infected to a healthy seed. These methods, however, do not differentiate between saprophytes and parasites. It is often easier to grow the seed in such conditions as are known to induce the parasitic fungi to attack the developing seedling, identification then depending on the symptoms produced. Thus in Sweden *Fusarium* infection in rye is determined by sowing seed under ground brickstone, which induces characteristic twisting of the shots. A variation of this method using sterilized sand has proved successful at East Craigs for testing oats for *Helminthosporium* as well as *Fusarium* spp. Some samples with 'official' germination capacity of around 95 per cent were found by this method to be perhaps 20–30 per cent infected, so that their value to the grower was reduced accordingly. In the case of oats infected with these diseases, the official figure is generally too favourable; but in others the reverse is true. *Ascochyta imperfecta*, the cause of black stem disease, is very common in trefoil samples and spreads very rapidly from seed to seed under the conditions of the official test in incubators, so that infection appears much higher than if the seed is sown in soil. This fungus illustrates another point: that certain seed-borne diseases are already well known to skilled analysts because of their effect on the appearance of the seed: trefoil seed severely infected by *Ascochyta imperfecta* is dark brown in colour and rather flat, while more superficial infection appears as thin black lines, which are, in fact, thick-walled hyphæ, visible on the seed to the naked eye. The analysts at East Craigs recognized these marks as indications of poor quality seed before we proved them to be specific fungal infection. There is no doubt that similar investigational and survey work on seed crops as well as seed after harvesting would yield most interesting results. There is now a very large industry in crop protectants, including seed disinfectants, but more attention should be paid to the production of healthy, vigorous seed. In this respect chemistry has outrun biology.

International Aspects of the Problem

These problems are not confined to Britain, for this country is involved in the international trade in seeds. In 1950 Britain imported seeds to the value of £4½ million and her exports were more than £2½ million. It may, of course, be argued that so far as seed-borne disease is concerned we must already have spread them around and received every possible foreign trouble and that it is now too late to shut the stable door. There are, however, still some diseases which might be imported here; bacterial blight of peas is one, and as it is most severe where frost pockets are found we might expect it to do great harm in Scotland to our expanding industry of growing peas for canning. Then a recent attempt to grow soya beans in Scotland was unsuccessful owing, at least in part, to seed-borne bacterial blight. Our seed came from Sweden, where the disease was unknown until a few years ago, when it was imported with seed of new American varieties.

To endorse this aspect of the problem, I should like to quote again from a paper read at the British Association at Cambridge in 1904. The speaker was R. H. Elliott, of Clifton Park, Kelso, to whom Stapledon has referred as the father of grassland husbandry. In his paper he appealed for seed testing to be begun officially in Great Britain. He died in 1914, the year that the Department of Agriculture for Scotland began the first advisory, as against statutory, seed testing. But he also asked that our farmers should be protected against the introduction of diseased seed from abroad. Now, almost fifty years after, it seems that there is hope that this also will be done.

Last year the Government issued the report of the committee set up to investigate the qualitative control of seeds. As a member of this committee recently said: "In the early stages of the development of seed testing practice, the emphasis appears to have been upon providing a ready means of assessing seed values, largely for the purpose of facilitating trade in seeds, without particular thought as to the value of the data to the grower".

The committee in its report has fully met this point and has further recommended, so far as health is concerned: (1) there should be an early extension of health surveys of home-grown and imported seeds; (2) there should be further research into methods of detecting seed-borne organisms, and to find suitable technique whereby seed samples can be examined speedily and accurately for the presence of diseases or pests; (3) seed-testing practice should be extended to cover health; (4) seed certification schemes should include inspection for disease.

Further, there should be close collaboration between the seed-testing stations and the plant pathology services and continued close liaison with the International Seed Testing Association.

The International Seed Testing Association, which had its first post-war meeting in Washington in 1950, has a Pathology Committee which will undoubtedly welcome this approach. Then in spring 1951 Great Britain signed the convention of the European Plant Protection Organization, under which we now commit ourselves to survey our crops for the presence of certain pests and diseases with the view of ensuring, in collaboration with the other subscribing countries, that those are not further spread abroad. One of the means of dissemination to which attention will be paid will undoubtedly be the seed.

In conclusion, therefore, the outlook for the further study of seed pathology in Great Britain and abroad is distinctly promising.

MINERALS AND MAGMAS: STUDIES AT HIGH TEMPERATURES AND PRESSURES*

By E. D. LACY

Department of Geology, University of Birmingham

A CARDINAL aim of the petrologist must be to explain the natural history of the rocks of the earth's crust in physico-chemical terms. To that end investigation of equilibria in dry silicate melts has been pursued for many years, with fruitful results, notably in the Geophysical Laboratory, Washington. Although studies on hydrous silicate systems were commenced there as long ago as 1914, their range has been limited until comparatively recently.

Water is an important component of magmas and of many minerals, and its presence in magmas is significant in several respects. The viscosity of the fluid is diminished and crystallization temperatures are lowered. Hydrous minerals such as amphibole or mica may be precipitated, though it does not necessarily follow that they will. At a late stage in the cooling a fluid rich in water may remain, capable of profoundly modifying either the early crystallized material or neighbouring rocks, or of transporting substances, such as sulphides, to a locality where lower temperature brings about their precipitation. When magmas reach the open air, the water they contain is largely fugitive, but when they cool at depth the water may be retained, at least for a time, because of the load of superincumbent rocks.

The part played by water in the metamorphic rocks is less well understood. Here the mineralogy and texture now displayed is due to recrystallization, which took place in the solid. Complex conditions attend such change and it is certain that water in trace amount has a considerable influence in promoting the breakdown of unstable minerals and the simultaneous growth of stable ones. When available in larger amounts, water may enter into the composition of metamorphic minerals such as chloritoid or staurolite. Water is undoubtedly instrumental in promoting the transfer of material both by processes of ionic diffusion and of solution. In metamorphism the rock load tends to promote closure of the system with respect to water.

---

* Substance of a paper read on August 14 before Section C (Geology) of the British Association meeting at Edinburgh.

Fundamental to all understanding of silicate crystallization phenomena, both in melts and in solid media, is a knowledge of phase stability relations. The range of temperature/pressure conditions to be covered is wide. Magmas are known to reach temperatures up to 1,185° C. Burial in the earth's crust involves a hydrostatic load increasing at the rate of 400 atmospheres per mile; hence experimental work faces formidable difficulties. A considerable number of workers, many in American laboratories, have contributed in this field. The designs for the necessary specialized apparatus can be classified broadly under three headings.

(1) *Closed bombs.* The material to be investigated is placed in a thick-walled vessel along with a calculated amount of water. The sample may be protected from contamination by the bomb wall by being placed in a crucible or by lining the bomb with noble metal. As in all similar work, it is desirable to bring about the reduction to room temperature very rapidly, in order to preserve the high-temperature products without change. This is done by quenching the bomb in cold water. Temperatures as high as 700° C. may be reached, but the pressure range is limited. The bomb typically is of about 100 c.c. capacity. Morey, Ingerson and Grunner are among the workers who have used this method, which is not preferred for precise work as the pressure developed on heating is known only approximately by computation, and leakage readily leads to inaccuracy.

(2) *Controlled autoclaves and bombs.* In this category come pressure vessels, varying largely in internal capacity, provided with pipe connexions to control valves and to gauges for measuring the pressure. The pressure may be generated solely by water placed in the bomb before sealing, or a high-pressure pump may be employed to inject water into the system as required. The vessel may be lined or the sample placed in a crucible as before. Variations of such apparatus have been designed which permit the sample to be refluxed or which expose the sample to percolation under pressure. The working space within apparatus of this type tends to diminish with increase in the severity of the pressure/temperature conditions.

The apparatus used by Bowen and Tuttle has yielded results of outstanding importance and is capable of withstanding an internal pressure of 1,000 atmospheres at a temperature of 1,000° C. The bomb is of very small capacity, and is rapidly cooled at the end of an experiment by using a retractable furnace and a water spray.

(3) *Apparatus using capsules.* In all the designs mentioned above, the pressure medium is water, a constituent of the system being investigated, which is thus an open one.

Goranson developed a technique for enclosing the solid sample and the volatile component in a thin platinum capsule. The system was thus completely protected from contamination, and furthermore several samples of varying composition could be dealt with at once. The capsules were heated in a furnace which was itself enclosed inside a pressure bomb, which latter was water-cooled. The pressure medium was carbon dioxide, supplied by an external pump. Under pressure, the sealed capsules collapsed until the pressure of water vapour within equalled the carbon dioxide pressure. With this apparatus runs were made at 1,200° C. under 4,000 atmospheres pressure. The drawbacks lay in the great cost and complexity of the apparatus and the apparently rather low rate of cooling.

A technique embodying new features has been developed in the Department of Geology, University of Birmingham. A sample is taken which may consist either of an artificial mixture, or of a cylinder of rock up to nearly ½ in. in diameter and large enough to make it possible to cut thin sections. The sample, together with any necessary water, is placed in a platinum capsule after the manner of Goranson. One or more capsules are placed in a pressure bomb connected to a supply of inert gas (argon) at pressures up to 600 atmospheres.

The bomb is long and narrow, one end only being heated and kept slightly higher than the other in order to prevent convective circulation of the argon. The other end is tapered in diameter, protrudes from the furnace, and, because of the low thermal conductivity of the metal, does not get much hotter than 100° C. Consequent upon the heating the pressure undergoes a large increase, but may be reduced to any required figure by releasing excess argon. The pressure/temperature conditions are maintained until equilibrium has been reached or some chosen period has elapsed.

The capsules can be transferred from the hot to the cold end of the bomb by tilting the bomb to a vertical position, where they are rapidly quenched in dense cool gas. This is made possible by mounting the bomb on a pivot and by making the connecting pipe to the bomb of flexible steel tubing having an external diameter of only 0·110 in. The equilibrium may thus be 'frozen' and the contents of the quenched capsules subjected to petrographical examination.

The maximum pressure reached so far is 1,800 atmospheres (nearly 12 tons per square inch), corresponding to a depth of burial of about 23,000 ft. (nearly 7 km.). The temperature on this occasion was 650° C. At 1,000 atmospheres the apparatus has been operated at 870°C. Development of the apparatus to cover a wider range of conditions is proceeding.

The pressure bombs have hitherto been made throughout from 'Nimonic' creep-resistant nickel–chrome alloy, developed for use in turbo-jet aircraft engines. Care must be taken to see that critical temperature/pressure limits are not exceeded. About 1,000 hr. of running, devoted to a series of exploratory experiments, has been accomplished.

Thus artificial thermal metamorphism has been produced in slate, with decomposition of chlorite to orthorhombic pyroxene completed at 650° C. At higher temperatures (760° and above), idioblastic andalusite was well developed after 100 hr.

Certain members of the amphibole family have been synthesized at 500° C. and 1,000 atmospheres.

The calcium carbonate/silica reaction is being studied, and preliminary results suggest that under anhydrous conditions decarbonation may proceed only at higher temperatures than has been predicted.

Recent research. The importance of this type of experimentation is demonstrated by the results of recent research in the United States.

For example, silica in any form is commonly regarded as being completely insoluble in water at ordinary temperatures. Under low pressures of liquid water a slight solubility can be shown, but this drops almost to zero as the critical temperature is approached. Under pressures of the order of 1,000 atmospheres of water vapour, however, a different state of affairs is found, for with increasing temperature the solubility progressively increases and has been determined up to a value of about ¼ per cent. These observations are clearly relevant to some problems of silica transport.

Unquestionably the most important family of minerals in igneous and metamorphic rocks is the feldspar family. Microscopic, heat treatment and X-ray studies have shown the group to be complex. Dry-melt investigation of feldspar crystallization has been laborious because the alkali feldspars take weeks or months to crystallize; but, by contrast, crystallization is completed within an hour in the presence of water vapour at a pressure of one thousand atmospheres. Recent high-pressure work has confirmed the existence of a high-temperature series and of a low-temperature series of plagioclase feldspars, with the consequence that a number of difficulties attending the identification of feldspars in lavas and porphyries are well on the way towards being cleared up. A further most important conclusion is that the stability relations observed between the alkali feldspars and leucite under dry-melt conditions broadly apply in the presence of water vapour under pressure, crystallization temperatures being much reduced to figures quite compatible with our current notions of magmatic temperatures. The value of earlier dry-melt work is thus confirmed.

A further notable research is that on the system $MgO–SiO_2–H_2O$. The temperature/pressure stability curves for substances such as pure forsterite, olivine, serpentine, enstatite, talc and periclase in the presence of water have been determined. The conditions under which serpentinization may and may not take place in Nature have been indicated, and the conclusion has been drawn that neither a dunite magma nor a serpentine magma is likely ever to exist. A possible mechanism for the formation of dyke-like masses of olivine rock in pyroxenites, depending on silica transport by water vapour, has been outlined.

The future. That hydrothermal research will play an increasing and vital part in formulating petrogenetic theory seems certain.

The keystone of further progress must be the study of the hydrostatic phase equilibria. Certain problems, such as the progressive decarbonation of a siliceous dolomite, discussed by Bowen and Tilley, offer a prospect of unusual interest and elegance. Replacement phenomena will continue to be enigmatic until the relevant phase-equilibrium conditions have been determined.

A topic of great interest concerns the primary or secondary nature of the water so copiously evolved as steam during volcanic eruption, and is a reminder that our knowledge of the solubility of water in molten silicates is fragmentary. Goranson's work on granite melts, twenty years ago, requires extension to melts prepared from other igneous rock types. The carbonatites present an intriguing puzzle in this connexion.

Quantitative assessment is yet barely possible of the magnitude of the forces responsible for the penetrative shearing movement and preferred orientation demonstrated in some metamorphic fabrics. This problem is a challenge to experimental ingenuity and, in addition, calls for a study of the kinetics of mineral crystal disintegration and growth at the atomic level.

Large-scale diffusion has been put forward repeatedly as an important petrogenetic process by many petrologists. There is no branch of the subject where quantitative laboratory evidence is so scant and where there is greater need for a strict physico-chemical treatment of the problem.

CHEMOTHERAPY OF TUBERCULOSIS

A COLLOQUIUM on the chemotherapy of tuberculosis was held in Dublin during July 10–13. It was sponsored by the Medical Research Council of Ireland, and the organization was in the hands of a small committee under the chairmanship of Dr. V. C. Barry. The meeting was international in character, the speakers being drawn from Great Britain, the United States, Germany, France and Ireland. There was a registered membership of 170, more than seventy of whom were overseas visitors, representing as well as the above countries, Switzerland, Holland and Sweden. The members came together for the first time on the eve of the opening at a reception given in Newman House by the President of University College and Mrs. Tierney.

The official opening of the colloquium in University College on July 10 was by the Minister for Health and Social Welfare, Dr. James Ryan. Prof. R. P. Farnan, chairman of the Medical Research Council, presided, and the attendance included the Taoiseach, Mr. de Valera. The colloquium was divided into seven sessions, each of which occupied a morning or afternoon. On Thursday afternoon the members had the honour of being received by the President of Ireland and Mrs. O'Kelly at Árás an Uachtaráin.

Each session was opened by a lecture and, after an interval for light refreshments, a discussion lasting about an hour and a half followed. The most interesting feature of the colloquium was that it brought together for four days the organic chemist and the biochemist, the bacteriologist, the pharmacologist and the clinician. The arrangement of the lectures was a logical one, beginning with the chemistry and biochemistry of the tubercle bacillus, followed by the organic chemists' approach to the problem of producing an adequate chemotherapeutic agent for tuberculosis. The story was continued with a description of the methods of preclinical evaluation of the agent. In the fourth lecture the present status of antibiotics in tuberculosis was assessed. At this stage the clinicians took over, and the last three lectures dealt with the thiosemicarbazones in tuberculosis, and the clinical evaluation of potential chemotherapeutic agents in pulmonary and urogenital tuberculosis. The formal and informal discussions which arose in this heterogeneous scientific gathering must prove of great value to all workers in this field.

Prof. Jessop presided at the first lecture, which was delivered by Dr. E. Lederer, on the chemistry and biochemistry of mycobacteria. This was an extensive review of the literature since 1940 on the carbohydrates, proteins and lipids of the bacilli. Dr. Lederer emphasized the extreme variability of the composition of mycobacteria and showed how it depends on environmental factors and the age of the culture. Perhaps of greatest interest was his account of the researches of his colleagues and himself on the mycolic acids. Their probable formula is $C_{88}H_{176}O_4$, which contains a —COOH, an —OH and an —OCH$_3$ group. Pyrolysis of the mycolic acid at 300° *in vacuo* gives *n*-hexacosanoic acid, $C_{26}H_{52}O_2$; chromic acid oxidation yields among other products stearic acid, *n*-hexacosanoic acid, hexadecane and a 1 : 16-dicarboxylic acid. Chromatographic purification on alumina has led to the isolation of two distinct, and apparently isomeric, mycolic acids (α- and β-). Degradation experiments indicate that a mycolic acid is a high molecular weight β-hydroxy acid with a long aliphatic side-chain in the α-position (α-*n*-tetracosyl-β-hydroxy acid). The difference between the α- and β-acids must reside in the C_{62} fragment, which still awaits investigation. Human virulent strains of *Myco-tuberculosis* contain methoxylated mycolic acids, while the *H*37 *RA* avirulent strain contains an α-mycolic acid free from methoxyl. The interesting new amino-acid, α,ε-diamino-pimelic acid, which Work isolated for the first time from the diphtheria bacillus, has now been found in all strains of Mycobacteria so far examined. Among other matters of interest covered in the lecture was the problem of acid-fastness. It seems that all our present knowledge of this phenomenon can be explained by the observation of Yegian and Vanderlinde, who have shown that, in the stained bacterial cell, the greater part of the dye is in solution inside the cell. Its introduction is effected by heating with a phenol solution of fuchsin, and it cannot be removed by acid-alcohol washing since the cell wall is impermeable to this solvent. Boiling alcohol does remove the stain. Acid-fastness is probably due, therefore, to the presence of a characteristic mycolic acid containing lipopolysaccharide in the cell membrane.

During the discussion which followed, Dr. C. Iland referred to work carried out with Prof. M. Stacey's team at Birmingham. A urea extract of young living tubercle bacilli gives a complex material which has the biological properties of fresh unheated tuberculin. It yields an electrophoretically homogeneous protein which gives a complement fixation test with human tuberculous sera. The use of urea for extracting living cells may prove of particular value in providing cheaply a tuberculin skin-testing reagent. Prof. R. A. Q. O'Meara pointed out that the subject of Dr. Lederer's address was the end-products of mycobacterial metabolism; of greater importance from the point of view of chemotherapy are the products of the intermediate phases of metabolism, the substances which are most elusive are likely to be the most important. Dr. D. Twomey referred to the isolation of branched-chain fatty acids from other natural sources; for example, the *iso*- and *anteiso*-series of acids isolated from wool-fat, and phytomonic acid from *P. tumefaciens*. These latter acids probably exist as such in Nature, unlike phthioic acid, which is now known to be an artefact. Dr. Twomey also provoked a discussion on 'permeability', which he suggested exists as a crude conception in the minds of many chemists and biologists.

In the second lecture, Dr. V. C. Barry described an organic chemist's approach to the chemotherapy of tuberculosis. He reviewed the work of his team, which is a unit of the Medical Research Council of Ireland. They have produced some drugs of potential value in tuberculosis and leprosy. *B*.53, a dialkyl succinic acid half-ester, has been used successfully in the treatment of tuberculosis of the urinary bladder. This substance has low *in vitro* activity in the presence of serum. A planned synthetical approach led to the production of a series of long branched-chain hydroxyamines which are much less antagonized by serum. One of these, *B*.390, a branched-chain pentadecylamine derivative, has shown a suppressive effect in guinea pig tuberculosis when given orally. A series of long-chain alkylpyrrolidines and piperidines was also described. In Dr. Barry's experience, this was the first example of a fatty compound exhibiting anti-tubercular activity *in vivo*, and it provides some justification for the long preoccupation of workers in this field with substances of a fatty nature. Another aspect of the work showed the development from the lichen product, diploicin, by successive synthetical modifications, of a series of phenazine dyes highly active against the bacillus in serum broth. One of these, *B*.283 (2-anilino-3-imino-5-phenyl-phenazine), has shown a suppressive effect in mouse and guinea pig tuberculosis. Dr. Barry described six types of compound which up to date are known to modify the disease in the guinea pig. These were all produced empirically. The testing of antitubercular compounds in liquid media enriched by serum can be relied on to make possible the selection of agents likely to exhibit activity *in vivo*. Dr. J. Barnes exhibited a series of photographs showing the effect of *B*.283 in a series of cases of lepromatous leprosy in Nigeria. In his view, *B*.283 is more rapidly effective than any other drug in current use for the treatment of this form of leprosy. A very lively discussion followed to which Dr. D. A. Peak, Mr. F. A. Robinson, Prof. J. Algar, Dr. Lederer and others contributed. The discussion centred for the most part on the question of the empirical versus the rational approach to chemotherapy. It was remarkable for the high level of honesty sustained, there being general agreement that no successful chemotherapeutic agent has yet been discovered by a completely rational approach. Prof. T. S. Wheeler presided at this session.

Dr. W. H. Feldman spoke on the preclinical appraisal of antituberculosis agents. He emphasized that certain prerequisites must be satisfied before a given agent is considered worthy of clinical trial. This necessitates the collection of a considerable amount of data from many experimental studies. He discussed in detail *in vitro* testing, the *in vivo* – *in vitro* test and the conduct of many *in vivo* screening routines. These included the use of the chick embryo, the baby chick, the rabbit (intracorneal infection), the mouse, the hamster and the guinea pig. No summary of this lecture is possible. The refinement and careful control of Dr. Feldman's *in vivo* experiments are wholly admirable. However, animal experimentation is not an end in itself, and in the present writer's view there is a stage in its development when further elaboration may lead only to results of purely theoretical significance. In the discussion, Mr. Francis compared the pathology of the disease in the monkey, dog and smaller animals. The dog does not develop much allergy, and must be regarded as a resistant animal. Dr. J. Ungar expressed the belief that *in vitro* testing is valueless unless carried out in complex media rich in protein. Substances with marked reticulocytic stimulation influence mice more than guinea pigs. The effect of streptomycin in experimental tuberculosis in the mouse is quite different from that in the guinea pig. Further contributors to the discussion were Dr.

A. Q. Wells, Dr. Carmichael, Dr. Conalty and Mr. W. Freeman. Prof. F. S. Stewart presided.

In the fourth session, the chair was occupied by Prof. T. G. Moorhead. Dr. George Brownlee opened the proceedings with a talk on the present status of antibiotics in tuberculosis. This was a stimulating and original contribution, which characteristically had little relevance to the title. Dr. Brownlee described six biochemical lesions which follow invasion by a tubercle bacillus: multiplication of the parasite, chemiotaxis of monocytes, inhibition of proteases, hypersensitivity effect, skin allergy and acquired resistance. Specific antimicrobial chemotherapy is associated only with the first. Three factors influence the effect of chemotherapeutic agents on a bacterial population: the efficiency of the agent, the effect of the number of the organisms, and the rate of emergence of resistant strains. Dr. Brownlee dealt at length with the role of hypersensitivity in the spread of the disease. He visualized the advent of an anti-anaphylactic drug which will effectively modify tuberculin hypersensitivity. This may be expected to revolutionize our present-day concepts of the limitations of conventional chemotherapy of tuberculosis. He also expressed the opinion that the evidence appears to be complete that a chemical entity exists in suitably prepared dead tubercle bacilli, which is antigenic and protective. Though this substance may be labile in character, he believed that ways will be found of extracting it. Opening the discussion, Dr. D. G. Madigan described the treatment of a group of patients with bacillary emulsion under the cover of effective chemotherapy with streptomycin and *p*-aminosalicylic acid. In 50 per cent of patients, it is possible to achieve desensitization as measured by the skin test (to 1 in 10) in six weeks. Dr. P. Swift described the treatment of tuberculous meningitis with streptomycin. In his opinion it is not now justifiable to use streptomycin by itself. The remainder of the session was devoted to a lively discussion on the origin and nature of streptomycin resistance, in which Prof. Kennedy, Dr. D. A. Mitchison, Mr. G. W. Dawson, Dr. J. Crofton and Prof. Julius took part.

The second half of the colloquium opened in Trinity College with Dr. Gerhard Domagk's lecture, Prof. W. R. Fearon presiding. Prof. Domagk said that three compounds have been used in the treatment of chronic tuberculosis infection: the thiosemicarbazones (conteben), streptomycin and *p*-aminosalicylic acid. All three are active against different types of tubercle bacilli both *in vitro* and *in vivo*. In the experimental animal, a combination of conteben and streptomycin has proved more effective than streptomycin alone or any other combination. Side reactions at first attributed to the thiosemicarbazone itself are to some extent due to dead or damaged bacilli. It is possible to obtain extensive fatty degeneration of the liver by injection of dead bacilli only. The thiosemicarbazones are being used extensively in South America and Central Africa for the treatment of leprosy. In the discussion, Dr. A. R. Martin pointed out that *TB III* (*p*-ethylsulphonylbenzaldehyde thiosemicarbazone) is better tolerated in man than conteben and produces much higher blood-levels with equal dosage. Dr. Barnes described a trial which he has conducted with a series of cases of tuberculoid and lepromatous leprosy. Conteben was effective in the former type, but very much less effective with the latter. In reply to Mr. Francis, whose experience has been that none of the partially successful tuberculosis and leprosy drugs have any appreciable effect on rat leprosy, Dr. Domagk pointed out that the strain of leprosy bacillus infecting man is quite different from the rat leprosy bacillus. It also emerged from the discussion that there is little information available as to the effect of thiosemicarbazones on streptomycin-resistant strains of tubercle bacilli.

The sixth and seventh lectures were mainly of interest to clinicians. Dr. Marc Daniels spoke on "The Clinical Evaluation of Potential Chemotherapeutic Agents in Pulmonary Tuberculosis". He described the various rigorous procedures and teamwork which alone can make a clinical trial of a new drug of value. Prof. J. M. O'Connor presided.

At the final session, Prof. J. McGrath presiding, Mr. J. T. D. Lane described his experience in the treatment of a number of cases of renal tuberculosis with streptomycin and a smaller number with *B*.283. The latter cases had failed to respond to streptomycin. It was clear that both drugs are more effective when dealing with early lesions. He thought it likely that a combination of the two drugs may prove more effective than either alone. In vesical tuberculosis persisting after nephrectomy, *B*.53 appears to be very effective. In this type of case, in his experience, streptomycin is only effective when the lesions are superficial.

It was a highly successful and lively conference, owing much of its success to the presence of workers interested in every stage of the chemotherapy of the disease, to the logical arrangement of the programme and finally to the fact that the limited number of contributions did not produce the mental indigestion frequently associated with gatherings of this kind. The chemists' contributions were tinged somewhat with melancholy, but not completely despairing. The biologists were optimistic and fruitful in theories. The bacteriologists among them appeared to be quietly confident that their routine procedures were adequate to any demands that might be made on them. The clinicians, however, as instanced by Dr. E. T. Freeman, were polite but firm in pointing out that the desired chemotherapeutic agent for tuberculosis has yet to be discovered.

A complete record of the proceedings will be published later this year as a special issue of the *Irish Journal of Medical Science*. VINCENT C. BARRY

THE FAWLEY REFINERY

FOR the past two years, ever since the first grader started site-clearance in July 1949, the word 'Fawley' has taken on a new meaning in British oil circles. The place itself was of small consequence on a comparatively little-known peninsula between Beaulieu River and Southampton Water, save for the existence of the original Esso Petroleum Company's oil refinery, in operation for some thirty years past. All this has now changed. The new Esso refinery, officially opened by the Prime Minister on September 14, is an accomplished fact, a triumph of American and British brains and skill, a monument to the close ties binding the two countries in peace as well as in war.

The history of this outstanding example of initiative and enterprise is as impressive as is the vista of the whole complex plant itself. Begun in 1949, it was actually completed this year four months ahead of schedule. The scheme involved clearing and levelling 450 acres of wooded gravel-land; construction of roads; laying down a railway system to connect up with permanent way to Southampton; erecting a huge building, 800 ft. long, 180 ft. wide and occupying more than 3 acres, first to house constructional materials, ultimately to serve as maintenance and machine shop; lay-out of a construction camp on site for 750 workmen; erection of a huge concrete plant with output of 140 cubic yards per hour, one of the largest in the world; installation of the main refinery units, in itself a colossal task of erecting and linking-up the bewildering maze of pipes, tanks, stills, furnaces and huge towers that go to make up a modern oil refinery. Add to this permanent houses for key-staff, a beautiful theatre and games building (social club) and it is at once obvious that the Fawley we used to know has been completely transformed into a self-contained city of potentially some 2,000 inhabitants; incidentally, some of the original inhabitants appeared to be almost Americanized.

A tour of the refinery during the day before the official opening provided unrivalled opportunity for studying the lay-out in technical detail. Crude oil is delivered by tanker to a specially constructed marine terminal, a 3,200-ft. jetty jutting into Southampton Water and connected to the main plant by a 2,000-ft. long approach road, constructed over salt marshland, carrying oil, steam and salt-water pipe-lines into the heart of the refinery itself. Thence fed to storage tanks, oil eventually passes through pipe-still furnaces to heat it up to 750° F.; thus vaporized, it enters the fractionating tower where condensation takes place at different levels on 'bubble trays'.

There are three fractionating towers here, two operating at atmospheric pressure, and a third under vacuum with steam distillation to deal with 'bottoms' from the other two. An outstanding feature is undoubtedly the huge catalytic cracking plant ('cat cracker') fed with gas oil, using a catalyst in an extremely fine state of particle division (technically known as 'fluid catalytic cracking'). A specially designed thermal-cracking plant converts lubricating oil and motor spirit into high-octane spirit plus gas. A polymerization plant determines increase in octane-rating of motor spirit obtained by distillation. A debutanizer tower, 113 ft. high, weighing 135 tons, separates butane and associated volatiles from motor spirit, designed to meet current vapour-pressure specifications. The copper sweetening unit removes corrosive compounds and evil-smelling vapours from motor spirit. Then there is the Edeleanu plant for improving burning qualities of kerosene; a hypochlorite plant for removing unpleasant sulphur compounds from kerosene and turbo-jet fuels; the lubricating oil plant, involving propane de-asphalting, phenol extraction, propane de-waxing and clay treatment processes. The oxidizing plant produces some well-known 'blown' grades of asphaltic bitumen; a 'specialty' unit manufactures anti-corrosive additives for lubricating oil; a hydro-desulphurization plant effects removal of sulphur from tractor-fuel.

In view of the serious shortage of sulphur at the present time, a vitally important unit under construction is the sulphur plant, for the conversion of hydrogen sulphide, released during varying stages of refining crude oil, into chemically pure 99·5 per cent rock sulphur. Full sulphur production is scheduled for early 1953; output will be of the order of 12,000 tons a year.

Fawley now assumes priority as the largest oil refinery in Europe. It cost £37,500,000 to build. When in full operation it will produce 6,500,000 tons of petroleum products a year; more than a million gallons of motor spirit a day; and nearly 30 per cent of present total demand for petroleum and products in the British Isles. Not least in these financially stringent times, this brilliantly planned and executed work will effect a saving in foreign exchange of more than 2 million dollars a week.

Someone concerned with the lavish series of publications which a great occasion like this official opening obviously presented had the foresight and sensitive imagination to commission H. E. Bates to write a commemoration "Fawley Achievement", "as a tribute to the vision, skill, and energy of all those who helped to plan and build it". Much praise was heard throughout the time of our tour of the new Fawley; but many read this tribute with a feeling that no one could have done it better than Bates, nor given to the sponsors of this great enterprise more encouragement for the future than is justly their due.

H. B. MILNER

OBITUARIES

Mr. G. Udny Yule, C.B.E., F.R.S.

GEORGE UDNY YULE was a member of a family distinguished for its scholarship and administrative talent. His father, Sir George Udny Yule, a very successful administrator in the Indian Civil Service, was one of three sons of Major William Yule, of the East India Company's service, who was born in 1764 and was in his day a well-known Orientalist; of the others, one, Lt.-Colonel Robert Abercromby Yule, a rising cavalry officer, was killed at Delhi in command of the 9th Lancers in 1857; the other, Colonel Sir Henry Yule, is remembered internationally for his authoritative edition of Marco Polo's travels. Udny Yule thus had an oral tradition of learning and of civil and military administration reaching back to the end of the eighteenth century. Udny Yule himself was educated at Winchester and University College, London. Science and engineering were his early interests, and he spent a postgraduate year under Hertz at Bonn on research into the passage of electric waves through dielectrics, which formed the subject of his first published paper. This field, however, was not very close to his heart, and he never reverted to it.

Udny Yule's scientific career proper began in 1893, when he joined Karl Pearson at University College, London, as lecturer in statistics. Pearson was laying the foundations of the science of theoretical statistics and it was not long before Yule himself was making fundamental contributions to the subject. For the next fifteen years he devoted himself mainly to the theory of statistical relationship, publishing basic memoirs on correlation (1897, 1907) and on association (1900). His work on association was later (1912) summarized in a further paper, and little has been added to it since; his work on correlation, in one form or another, continued throughout most of his life.

From 1902 onwards Yule gave a series of Newmarch Lectures which in 1911 were amplified and published as "An Introduction to the Theory of Statistics". This famous text-book remained for many years the only extensive account of the subject. There are very few students of statistics even to-day who do not owe something to it. With numerous subsequent revisions it has reached its fourteenth edition and appears to be maintaining its place in spite of its now numerous competitors; it has been translated into several languages, notably Czech and Spanish.

In 1912 Yule went to Cambridge, where he became a Fellow of St. John's College and University reader in statistics. His academic career was interrupted by the First World War, and he spent the four years 1914–18 in the Contracts Department of the Board of Trade, his services being recognized by a C.B.E. Thereafter, scientific recognition followed by easy stages. He was elected a Fellow of the Royal Society in 1921, and president of the Royal Statistical Society in 1923, having been awarded that Society's highest honour, the Guy Medal in Gold, in 1911. He was honoured by several foreign societies and in 1947 was made an honorary member of the International Institute of Statistics.

During the phase from 1912 until 1927, Udny Yule's work fell into two classes. In conjunction with Major Greenwood he laid the foundations of the study of accident distributions, a subject which nowadays has a much wider field of application than when Yule began on it. His interest in statistical relationship found expression in a paper of 1921 on time correlation and one in 1926 on 'nonsense correlations'. His work culminated in a famous paper in 1927 on sunspots, which forms the starting point of the modern theory of oscillatory time-series.

In 1931 Yule retired and, characteristically, took up flying as a hobby. He was very proud of obtaining a pilot's certificate *A* at the age of sixty; but unfortunately his heart gave serious trouble shortly afterwards, and the remaining twenty years of his life were spent in comparative seclusion at Cambridge, which he rarely left.

His main scientific work was now at an end; but the literary and philological interests of his family began to show themselves. Moved by doubts cast on the traditional attribution of the authorship of the "Imitatio Christi" to Thomas à Kempis, he was led to a statistical study of literary vocabulary, on which he published his last book in 1944. His strength then failed, and during the closing years he was able to accomplish very little. He died at the Evelyn Nursing Home at Cambridge on June 26, 1951, at the age of eighty.

Yule's work is characterized by its originality, its thoroughness and a wonderful insight into the problems which he studied. A great many of the basic ideas of statistical theory can be traced back to his papers, where they find expression with the modesty and simplicity of genius. He was one of the statistical giants of his age. In spite of some provocation he never embarked on controversy, and his objectivity towards his fellow statisticians is without blemish. In character he was kindly and sociable, with opinions soundly based, firmly held but moderately expounded—a thoroughly lovable man.

M. G. KENDALL

WE regret to announce the following deaths:

Dr. K. C. Bailey, registrar of the University of Dublin, and during 1935–47 professor of physical chemistry in the University, aged fifty-five.

Sir Eric Maclagan, K.C.V.O., C.B.E., during 1924–45 director and secretary of the Victoria and Albert Museum, London, on September 14, aged seventy-two.

Prof. F. W. Oliver, F.R.S., emeritus professor of botany, University College, London, on September 14, aged eighty-seven.

NEWS and VIEWS

Higher Technological Education in Great Britain

THE statement of Government Policy for the Development of Higher Technological Education in Great Britain (London: H.M. Stationery Office, 3*d*. net) issued on September 20 sets forth the Government decisions on the report of the National Advisory Council on Education for Industry and Commerce, but gives little indication of real policy in either technical or technological education. The two are not clearly distinguished; but so far as the former is concerned, the policy would appear to be 'the mixture as before'. In regard to technological education, the chief feature is the rejection of the idea of a technological university, whether an entirely new institution or by the expansion of some existing institution. The cost of such a proposal is estimated at £6 millions, and its creation by either method is regarded as requiring too large a diversion of available resources. Instead, a policy of diversified expansion is to be pursued. The universities are to be encouraged to expand their existing departments in technology and to institute postgraduate courses in particular fields of technology, while the University Grants Committee is considering the possibility of expanding much more considerably at one or two places. On this side it will not be possible to pass judgment until the University Grants Committee indicates its proposals for the next quinquennium; but the Statement intimates that the Government proposals for making improved financial assistance available for selected technical colleges and courses will be announced shortly.

According to the Statement, some sixty technical colleges in England and Wales and six in Scotland provide higher technological education; but until these further details are made public it cannot be judged whether the proposed policy will yield any effective return and not lead to waste of resources through excessive diffusion. The Government has accepted the dubious proposal to establish a College of Technologists—though the use of the title 'Royal' is temporarily to be withheld—with responsibilities limited to granting awards of associateship, etc., and for the approval of courses for this purpose. Until the details of the Government's own proposals for selected technical colleges and those of the University Grants Committee in regard to the universities are made known, the value of the proposals cannot be judged. The trend of the Statement indicates a desire to court the favour of the universities and of the local education authorities, rather than to deal imaginatively with the real issues and to ensure that existing resources are used to the best advantage, from the national, and not from any sectional, point of view.

City and Guilds of London Institute

At a special general meeting of the members of the City and Guilds of London Institute, held at Skinners' Hall on September 21, H.R.H. the Duke of Edinburgh was elected president. The first president was King Edward VII, when Prince of Wales; but on his accession to the throne he became visitor in accordance with the Institute's Royal Charter granted in 1900, and the office had since remained vacant. This further connexion with the Royal Family is a high tribute to the Institute's independent work extending over a period of seventy years. It is also a reminder that much still remains to be done by all concerned with scientific and technological education, as the Duke of Edinburgh so clearly indicated in his presidential address to the British Association this year.

The Institute was founded by the Corporation and certain of the Livery Companies of the City of London in 1878, during the period which His Royal Highness described as the high-water mark of British industrial expansion. There was a great need for better scientific and technical grounding for those engaged in industry, and the Institute accordingly set itself to meet this need by founding Finsbury Technical College, the Central Institution (now the City and Guilds College) and the Art School at Kennington. Concurrently the Institute, having taken over the technical examinations of the Royal Society of Arts, began to build up the Department of Technology, the syllabuses and certificates of which are so well known to industry and to countless students and teachers in technical colleges. This is a long list to the credit of one body, and the common parentage is not always appreciated. The influence of each, from craft to professional level, on technological training and education has been considerable. This year recalls the 1851 Exhibition, which was also of practical significance to the Institute, for the City and Guilds College is among the educational institutions built on the site purchased with the proceeds of that great enterprise of Prince Albert.

United Nations Technical Assistance to Underdeveloped Countries

In view of the demands which the Colombo Plan and other schemes for technical assistance to the underdeveloped areas of the world may make upon British and other resources, particularly in scientific and technical man-power, the pamphlet "United Nations Work and Programmes for Technical Assistance" (pp. 40; New York: United Nations; London: H.M. Stationery Office; 1951; 15 cents. 1*s*.), issued by the United Nations Department of Public Information, makes a welcome appearance. Its forty pages contain a clear explanation of what is meant by technical assistance, how the programme came into being, the principles which determine the selection of experts or of projects, the way in which the programme works and is administered, and where the particular responsibilities lie, as well as the way in which it is related to other programmes of technical assistance. An annexe records the technical assistance given in 1950, including the countries aided, and a brief bibliography indicates where further information about the technical assistance work of the United Nations and the Specialized Agencies may be found. The pamphlet is strictly factual and should assist in the discussions of a subject that, as the recent report of the Advisory Council on Scientific Policy indicates, is likely to become increasingly important. While it outlines what is required of the assisted countries and should help to keep discussion free from prejudice, there is one important omission which doubtless is unavoidable in a pamphlet of this nature and length: it does not indicate the factors, such as population pressure, which may determine, independently of the merits of the programmes themselves, the success or failure of technical assistance. Such factors must receive full recognition in deciding on the allocation of limited scientific and technical resources, whether from the United Kingdom or elsewhere.

Natural Resources of Canada: Annual Departmental Report for 1948–49

The report of the Mines, Forests and Scientific Services Branch of the Department of Mines and Resources, Canada, for the year ended March 31, 1949 (pp. 117; Ottawa: King's Printer, 1950), which has been reprinted from the Department's annual report, covers the activities of the Bureau of Mines, Dominion Forest Service, Geological Survey of Canada, Surveys and Mapping Bureau, Dominion Water and Power Bureau, Geographical Bureau, National Museum of Canada and the Dominion Observatories. Special stress is laid upon the continued success of drilling operations in the new oil-fields in Alberta, and Canada's dependence on foreign supplies is expected to diminish considerably; besides a large increase in production for 1949, a considerable expansion of refining facilities was anticipated. Closely related to these developments are developments with natural gas which may markedly affect the economy of the country. There were also important developments in relation to iron ore, titanium and uranium. The salt industry continued to expand, as well as the forest industry, and exports of pulp and paper attained new records. Increasing attention is being given to the depletion of forests, and especially to more efficient utilization of the hewn wood, but losses through forest fires were again high. The Geological Survey's facilities for assisting in the search for radioactive minerals were extended, as well as those of its Geophysical Section for dealing with the plotting of magnetic data acquired with the airborne magnetometer. A pilot plant for the separation of bitumen from the bituminous sand of northern Alberta was ready for operation at the end of the year, and the practicability of structural steel welding in Canada under winter conditions has been demonstrated. Work on the use of red-stained jack-pine in sleepers and poles is likely to conserve timber supplies, and the Surveys and Mapping Bureau has been considerably expanded to meet the increased demand for maps in the study and development of Canada's natural resources.

Training for Social Work

An international survey of training for social work has been prepared by the United Nations Department of Social Affairs to provide the Social Commission and the Economic and Social Council with a detailed description and analysis of the methods of training of social workers in various countries. The study is based on reports submitted to the United Nations Secretariat and analyses the various conceptions of social work revealed in the definitions submitted. It also contains a survey of the general systems of education for social work that have been evolved for the professional training of social workers. In addition, it presents a comparative analysis of the non-curricular and curricular aspects of schools of social work in forty-one countries; the general body of knowledge imparted to social work students; the general pedagogical methods used in the preparation of social workers; the administrative and financial aspects of schools of social work; the duration of the period of study; the relative importance assigned to the subjects included within the curriculum; and the methods by which theoretical knowledge and technical proficiency are imparted. The study also reviews United Nations' activities relating to training for social work and offers suggestions for future action in the national and international fields. Three useful appendixes contain statements of the definition of social work and the social worker received from various countries; a descriptive summary of the organization and programme of study of one school of social work in each of forty-one countries; and a directory of schools of social work in all countries which have established such schools. Copies of the document may be obtained from H.M. Stationery Office, price 15*s*.

National Research Development Corporation

The President of the Board of Trade has made three new appointments to the membership of the Corporation, and has re-appointed those members whose initial period of service recently expired. The Corporation now comprises: Sir Percy Mills (*chairman*); Lord Halsbury (*managing director*); Prof. P. M. S. Blackett; Prof. E. C. Dodds; Sir John Duncanson; Sir Edward Hodgson; W. E. P. Johnson; J. F. Lockwood; Sir Rowland Smith; Sir Edward de Stein; and Sir Henry Tizard. The new members are: Mr. Lockwood, managing director of Henry Simon, Ltd., and a director of other engineering companies; Sir Rowland Smith, chairman of the Ford Motor Co. and chairman, or a director, of a number of associated companies; and Sir Henry Tizard, chairman of the Advisory Council on Scientific Policy and the Defence Research Policy Committee.

"Blue Sun and Moon"

Referring to their communication under this title on p. 554 of this issue, Dr. William Paul and Prof. R. V. Jones write: "Since our communication was written, Mr. R. R. Wilson, of the Royal Observatory, Edinburgh, has given an account, before Section A (Mathematics and Physics) of the British Association during the recent Edinburgh meeting, of his observations on the blue sun of September 26, 1950, and his deductions. Mr. Wilson succeeded in making spectrophotometric measurements of I_N/I_B for various wave-lengths, where I_B and I_N are the intensities of the blue and normal suns. The observed curve of log I_N/I_B against wave-length shows a minimum in the blue. Mr. Wilson has compared his results with theoretical curves as calculated by Van de Hulst and others and deduces a numerical value of $d(m-1)$, where d is the diameter of the scattering particles and m is the refractive index. He has discussed the probable nature of the scattering particles."

The Night Sky in October

New moon occurs on Oct. 1d. 01h. 57m., U.T., and full moon on Oct. 15d. 00h. 51m. The following conjunctions with the moon take place: Oct. 14d. 04h., Jupiter 5° S.; Oct. 26d. 17h., Mars 2° N.; Oct. 26d. 23h., Venus 0·04° S.; Oct. 28d. 18h., Saturn 5° N. In addition to these conjunctions with the moon, Mars is in conjunction with Regulus on Oct. 3d. 03h., Mars being 0·9° N. Mercury rises about an hour before the sun on October 1 and is in superior conjunction on October 13; it is too close to the sun to be seen during the remainder of the month. Venus, a morning star, rises at 3h. 10m., 2h. 40m. and 2h. 35m., on October 1, 15 and 31, respectively. The stellar magnitude of the planet is −4·3, and the visible portion of the disk varies between 0·20 and 0·42. Mars rises soon after 2h. throughout October and can be seen in the constellation Leo, close to Regulus early in the month. Jupiter is in opposition on October 3, rising early in the evening throughout the month and setting at 6h. 10m., 5h. 0m. and 3h. 50m., on October 1, 15 and 31, respectively. Saturn is too close to the sun in the early part of the month to be seen but rises 1h. 20m. before sunrise on October 15 and 2h. 40m. before sunrise on October 31. Occultations of stars brighter than magnitude 6 are as follows: Oct. 10d. 17h. 57·4m., δ Capr. (*D*); Oct. 10d. 18h. 50·4m., δ Capr. (*R*); Oct. 17d. 23h. 14·2m., *q* Taur. (*D*); Oct. 17d. 23h. 36·5m., 20 Taur. (*D*); Oct. 17d. 23h. 57·7m., 16 Taur. (*R*); Oct. 18d. 0h. 28·3m., *q* Taur. (*R*); Oct. 18d. 0h. 32·6m., 20 Taur. (*R*); Oct. 18d. 0h. 55·9 m., 21 Taur. (*R*). (*D*) and (*R*) refer to disappearance and reappearance, respectively, and the times refer to observations made at Greenwich. Strong moonlight towards the middle of the month will prevent good observations of the Orionid meteor shower.

Announcements

Prof. W. T. Astbury, professor of biomolecular structure, University of Leeds, has been elected a corresponding member of the Istituto Lombardo di Scienze e Lettere.

The Lord President of the Council has appointed Sir Eric Rideal, professor of physical chemistry in King's College, University of London, to be a member of the Advisory Council for Scientific and Industrial Research from October 1. Prof. H. W. Melville retires from the Council on September 30, on completion of his period of service.

An informal conference on cationic polymerization and related topics will be held in the University College of North Staffordshire during March 24–26, 1952. Intending contributors should send the titles of their papers not later than October 31, and summaries not later than January 15, 1952. The fee, comprising also meals and accommodation, will be approximately £3. All communications should be addressed to Dr. P. H. Plesch, The College, Keele, Staffs.

The Meldola Medal is the gift of the Society of Maccabaeans and is normally awarded annually. The next award will be made early in 1952 to the chemist who, being a British subject and less than thirty years of age on December 31, 1951, shows the most promise, as indicated by his or her published chemical work brought to the notice of the Council of the Royal Institute of Chemistry before December 31. Communications should be addressed to the President, Royal Institute of Chemistry, 30 Russell Square, London, W.C.1, the envelope being marked "Meldola Medal".

PHYSICS OF SOCIAL EQUILIBRIUM

THE paper read by Dr. R. Fürth, reader in theoretical physics in Birkbeck College, London, on August 15 at the Edinburgh meeting of the British Association under this title broke new ground, and the enterprise of the author is a welcome sign that the natural scientist is making even more strenuous endeavours than he has done in the past to apply the concepts he has developed to social problems. A large amount of the work which has been carried out in the 'natural' and 'social' worlds has always been of common interest to both, as, for example, the theories of evolution developed during the nineteenth century. Nothing but good can come from the sharing of ideas and co-operative endeavour, provided that there is a clear understanding that there are fundamental differences between, as it were, the 'climates' of the two worlds, and that what is useful and will prosper in one world will not necessarily survive in the other.

At the beginning of his paper, Dr. Fürth has underlined the dangers that beset us when this proviso is neglected. As he points out, the use of physical models for the understanding of social phenomena has often led to gross over-simplifications, and sometimes to disastrous misunderstandings. Examples cited in the paper include the familiar analogies which are drawn between the concepts of 'forces', 'balances' and 'equilibrium', which refer to the properties of solid structures, and the behaviour of social communities. The model of a rigid body is, in fact, often used in popular literature to explain the processes of social change. Expressions such as 'the swing of the political pendulum' have crept into everyday language, and the result, as Dr. Fürth points out, is to give the ordinary citizen the erroneous belief that "present difficulties will in due course resolve themselves automatically by the working of some miraculous social mechanism".

Dr. Fürth is, of course, correct when he finds the distinction between mechanical machines and social communities in the *voluntary* working of the latter, and in the *intelligent* co-operation which exists between its parts. But he tends to over-state his case when he argues that the use of statistical techniques in the analysis of human behaviour may tend to predictions that are "completely wrong". It is perfectly just to point out that "the fate of the spinning ball is in no way influenced by the results of previous games", and to argue that predictions of social, as contrasted with natural, events are often invalidated by the mere fact that they have been communicated to the persons whose behaviour was the subject of the experiment. But in this case the statistician's 'other things' are not 'equal', and the validity of statistical techniques is left unimpaired. Indeed, the value of prediction in the social field often lies in the fact that processes of social change can be set in motion to avoid the occurrence of such phenomena as population decline that would otherwise take place.

Dr. Fürth's criticism of statistical techniques is, surely, only valid if the end-product of social science is accepted as the understanding of the very purposes of human life itself, and few social scientists would be presumptuous enough to maintain anything so outrageously ambitious. The main achievements of social scientists during the past generation have been to demonstrate that the extent to which human society is, in fact, 'voluntary' and human co-operation 'intelligent', is very much less than the intelligent Victorian believed or the common-sense man of to-day assumes. It is the unconscious influences that determine our everyday behaviour, and the undirected processes that shape the structure and development of human societies, to which we are turning our attention in increasing degree, and it is in that area of human experience that the methods of the natural sciences are most directly applicable. To what extent the unconscious can and should be made conscious, and the undirected brought under control, remains to be seen. But much (perhaps everything) that makes for human survival depends on it.

Dr. Fürth ends his paper with a plea for the application of statistical mechanics, the branch of theoretical physics which has been developed for the theoretical treatment of many physical phenomena, to the problems of social organization. In so far as the principal field of application, as Dr. Fürth points out, has been to the physics of systems or 'assemblies' of very large numbers of identical particles, there is a strong probability that social scientists will find in this branch of knowledge a valuable means for unravelling the very baffling problems which arise from the interaction between the individuals which compose a social group or community. But to argue more than this at the present time is highly misleading. To compare (as Dr. Fürth does) the behaviour of 'communities' of crystals of pure substances with that of human societies is surely to create the confusions and encourage the errors which he so rightly deplores at the beginning of his paper. To ascribe the political stability of the United Kingdom and of the British Commonwealth of Nations to "the soundness of their structures on the physical principles of strength of material bodies" is, at least, a gross over-simplification. The value of "statistical mechanics" for the social scientist must first be demonstrated by painstaking experiment in the factory working group or the housing estate neighbourhood before such generalizations are permissible.

T. S. SIMEY

FIELD-WORK IN ZOOLOGY

A DISCUSSION on "Zoology at the Marine, Freshwater and Field Stations" was held in Section D (Zoology) of the British Association at Edinburgh on the morning of August 13. Mr. E. Ford, director of the Marine Station at Millport, opened the discussion by describing the development of marine stations in Great Britain and abroad. His own station at Millport had as its first home the *Ark*, originally a floating laboratory moored in a submerged quarry at Granton, Edinburgh. Whereas in former days the attitude was that of the general practitioner in the broad field of zoological inquiry, the present tendency is to think and work as specialists. Specialization not only canalizes aim and effort but also leads almost inevitably to specialized institutions. The majority of the stations in Great Britain were at first committed by constitution to study the life of fishes in the interests of British commercial fisheries.

To-day, however, the main responsibility for this highly important public service is exercised directly by the Government through its different fishery laboratories and its permanent boards and commissions. There are special staffs and special laboratories dealing with other aspects. The Oceanographic Laboratory in Edinburgh, engaged in a plankton survey by means of automatic plankton recorders towed behind commercial ships; the newly constituted National Institute of Oceanography, devoting special attention to marine physical science; and the new Institute of Seaweed Research were quoted as examples.

Mr. Ford believes that there is a limit to the size of the station, beyond which it begins to lose that priceless opportunity for close personal association between all within its walls. A station that is too small has limited activities; a station that is too large is an impersonal workshop, and not a meeting place for colleagues.

Dr. H. D. Slack described the field laboratory on the west shore of Loch Lomond which was established in 1946 by the Zoology Department of the University of Glasgow for the study of life in fresh water and of insect life on land. This, being purely an extension of the Department of Zoology, has the same dual role of research and teaching. In the undergraduate course during the summer term, the benthic fauna of the Loch along a transect from the shore forms a part of the practical work, together with methods of hydrological investigation and a study of the plankton. Students specializing in freshwater biology undertake a research problem for presentation as a thesis in their honours degree examination.

Loch Lomond is divided into two by the Highland Boundary Fault: a shallow southern portion not more than 30 metres deep on Lower Carboniferous and Devonian rocks, and a long and narrow northern part on Cambrian mica-schists and grits with a greatest depth of more than 200 metres. Preliminary investigations of the hydrological data show that a thermal stratification is established in the deeper portion in July, but not in the shallow portion. The Loch is in general oligotrophic in character, but less so in its southern than its northern half. How far this tallies with the distribution and quality of the fauna has still to be determined, for very few observations have been made on the fauna of the deeper waters. Perhaps the distribution of fishes may afford evidence of the Loch's differential evolution. A perch-pike stage has been reached in the lower loch, and roach are common below the Highland Boundary Fault, while brown trout are still numerous throughout the Loch and appear to be more so toward the northern end. Only a reference in an old statistical account of 1796 stands as evidence of char having once been present, but the powan (*Coregonus clupeoides*) is abundant. This fish lives for the most part in deep water, feeding on pelagic plankton, but appears in large shoals in littoral regions during the summer.

Prof. L. A. Harvey's paper on field zoology at Exeter was read for him in his absence by Mr. J. Delany. He described the development of an annual course on ecology organized as a fortnight's camp under canvas. This started with only two students in 1932, was thrown open to the Universities of Britain in 1935, and now accommodates up to thirty students with a staff of three or four teaching members. Ladram Bay near Sidmouth was selected as a site from which ready access to as wide a variety of habitats as possible could be had. The programme is varied each year according to the interests and needs of the students and also of the staff. But whatever the individual items, the major aim has been to teach the principles and practice of ecological investigation rather than merely to elucidate the ecological relations within any given habitat. Quantitative methods used include ¼-m. sq. transects on the shore and salt-marsh and on moorland and bog, the use of random squares for assessing, in particular, plant populations, methods of estimating hardness, salinity, oxygen content, *p*H of water and various methods of trapping small mammals and of estimating the vegetation pattern associated with their distribution. Special techniques have been used at different times for assessing grasshopper populations, quantitative scoops for mud and gravel communities in the River Otter and the like.

Prof. Harvey, after brief mention of a fortnight's course of field studies for teachers which continued for some years but is no longer arranged, described a third project, namely, the investigation of the ecology of Lundy Island in the Bristol Channel. The Lundy Field Society has been founded, membership of which is open to anyone interested, and by this means it is proposed to weld together the interests and activities of both professional biologists and amateur naturalists. So far this has been most successful on the ornithological side, and an ornithologist is maintained as warden. Considerable progress has been made on surveys of the shores of the Island. Here, within a very small compass, exists a high degree of variation—from extreme exposure on the granite of the west and south-west to full shelter on the east, while entirely different shore conformations are provided by the little tag of slate at the south-eastern tip.

Dr. J. P. Harding, in expressing a museum attitude to work at marine, freshwater and field stations, said that there are many problems in zoology which can be best attacked by uniting the efforts of workers in many different fields. Among the most important are those concerning the mechanisms of evolution and the origins of species. The museum worker has helped with these problems not only by naming, describing and classifying species, but also by studying their geographical distribution. Animals living at any one time in a small area such as the British Isles can be divided into a number of quite different species. Each species consists of a population of individuals distinguished from other species by the possession of a number of characters which, while they will vary to a greater or lesser extent from individual to individual, do not do so sufficiently for there to be any overlap between one species and the next. Over a large area, however, such as that of a continent, the population living at one end may be quite distinct from that at the other; but there may be a complete series of intermediate populations in between. The herring gull and the lesser black-backed gull provide a very good example. These behave in Great Britain as two quite distinct species with no intermediates; yet a continuous series of birds linking up the two can be found by studying these gulls throughout their geographical ranges. Herring gulls extend in North America from Labrador to Alaska, and lesser black-backed gulls in Europe from Norway to Siberia. The birds in Siberia are, however, very much more like the herring gulls of Alaska than the lesser black-backed gulls of Britain, although they are linked with the latter by a more-or-less continuous population. This is an extreme case of a continuously varying species, the end members overlapping but not inter-breeding.

The museum man with large collections of specimens from all over the world is in a favourable position for studying this type of geographical distribution; but it is the field-worker who can best study local variations of physiological characters, and these, being more intimately concerned with the animals' welfare, are often of great adaptive value. The museum worker is constantly finding differences between his specimens and being unable to decide whether these are due to the effects of the environment or not; only someone in the field can find out for him.

The president of Section D (Dr. C. F. A. Pantin), Mr. J. Colman, Mr. H. C. Gilson, Prof. H. R. Hewer, Prof. A. D. Hobson and Dr. C. F. Hickling took part in the discussion which followed. Dr. Pantin drew a distinction between biology and the physical sciences; workers in either research or teaching in biology have to derive general principles from very complex situations. The solution of biological problems, he said, often comes from unexpected directions, and can only be appreciated by those with a direct contact with the animals themselves.

TRANSFER OF LIGHT ENERGY WITHIN THE PIGMENT SYSTEMS PRESENT IN PHOTOSYNTHESIZING CELLS

By L. N. M. DUYSENS

Biophysical Research Group, Utrecht

IN investigations[1,2] on photosynthesis of diatoms, it was found that light quanta absorbed by the carotenoid fucoxanthin brought about as strong a fluorescence of chlorophyll *a* as light absorbed by chlorophyll *a* itself; thus, energy transfer occurs with an efficiency of one hundred per cent.

With more refined spectral methods, we have carried out a more general investigation of the energy transfer between pigments within the photosynthetic apparatus. The work covers the main groups of photosynthesizing organisms. Fluorescence spectra were determined by means of a monochromator and a slightly modified photoelectric A.C. amplifier as described by Milatz and Bloembergen[3]. Various wave-lengths of incident monochromatic light were used for exciting fluorescence; the absorption of the incident light in the cells was also determined. Action spectra of photosynthesis of the same organisms were determined by J. C. Goedheer in this Laboratory, using a polarographic method[4]. In some cases phototaxis action spectra, which may be assumed to correspond with the photosynthesis action spectra[5,6], have been measured with Manten's bacteriophotometer[5].

The main photosynthetic pigment in purple bacteria, bacteriochlorophyll, probably occurs in three distinct bacteriochlorophyll-proteins[7], distinguished by absorption maxima at 800, 850 and 890 mμ respectively. For the sake of convenience they will be called here *B* 800, *B* 850 and *B* 890.

By examining fluorescence spectra, it was found that only *B* 890 shows fluorescence.

Transfer of light energy from the carotenoids to *B* 890 was found to occur in *Chromatium* strain *D* and in a strain of *Rhodospirillum molischianum* with efficiencies of 35–40 and 50 per cent respectively. If complete transfer to *B* 890 occurred, the fluorescence action spectrum (corrected for absorption) would be proportional to the absorption spectrum of the bacteria, also between 450 and 550 mμ, in which region the absorption is mainly due to the carotenoids. If, on the other hand, no energy transfer to *B* 890 occurred, the fluorescence action spectrum would be proportional to the absorption spectrum of bacteriochlorophyll, and only a small activity for fluorescence excitation would be found between 450 and 550 mμ. The fluorescence action spectrum actually found (Fig. 1) proves that a partial transfer takes place. Fig. 1 further shows that the action spectrum for *B* 890-fluorescence is proportional to the action-spectrum for phototaxis (or photosynthesis). This indicates that the carotenoids take part in photosynthesis only by transferring their excitation energy to *B* 890.

Additional experiments in the infra-red region showed that *B* 800 and probably *B* 850 also transfer their excitation energy to *B* 890.

By determining fluorescence spectra for various wave-lengths of incident light, it was found that, in vital cultures of *Chlorella*, only chlorophyll *a* shows fluorescence. From the fluorescence action spectrum it could be concluded, in an analogous way as above, that an almost complete transfer of excitation energy from chlorophyll *b* to chlorophyll *a* occurs, which is in agreement with the high efficiency of chlorophyll *b* in photosynthesis.

In solutions of about 10^{-6} *M* of both pigments in acetone, transfer of energy from chlorophyll *b* to *a* was also established, the efficiency being about 50 per cent.

The rather complicated fluorescence spectra of the red algæ *Porphyra laciniata* and *Porphyridium cruentum* and also of the blue alga *Oscillatoria* sp. could be analysed reasonably well in terms of fluorescence spectra of chlorophyll *a*, of the phycobilins and of an unknown pigment with a fluorescence maximum at about 725 mμ.

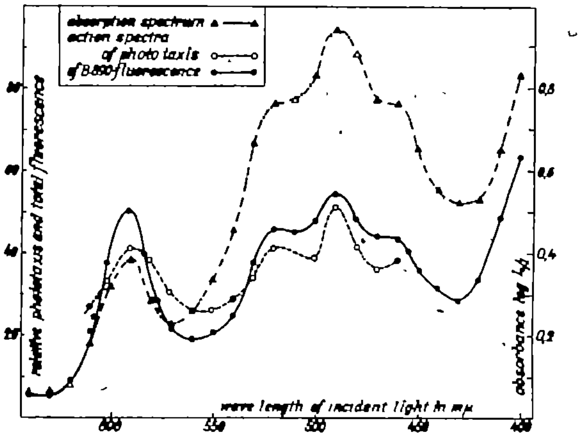

Fig. 1. Absorption spectrum, and action spectra for phototaxis and for *B* 890-fluorescence of *Chromatium* strain *D*. The absorption peak at 590 mμ is due to bacteriochlorophyll, the absorption between 450 and 550 mμ mainly to carotenoids. The carotenoids appear to be active with about the same efficiency both for phototaxis and for bacteriochlorophyll fluorescence. The fluorescence molecule is *B* 890 (see text)

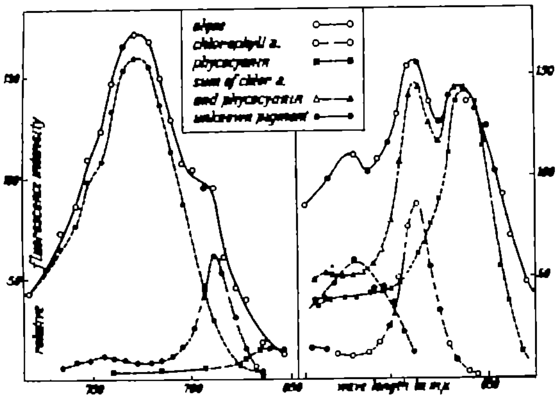

Fig. 2a. Fluorescence spectrum of *Porphyra lacineata*; relative fluorescence per quantum of incident light absorbed by chlorophyll *a* at 420 mμ (70 per cent of the absorption is due to chlorophyll *a*)

Fig. 2b. Fluorescence spectrum of *Porphyra lacineata*; fluorescence per quantum absorbed by all pigments at 546 mμ (approximately 70 per cent of the total absorption being due to phycoerythrin)

The fluorescence of chlorophyll *a* in *Porphyra lacineata* (Fig. 2b) per quantum absorbed by all pigments (incident light of wave-length 546 mμ) appears to be stronger than the chlorophyll *a* fluorescence (Fig. 2a) per quantum absorbed by chlorophyll *a* itself (incident light of wave-length 420 mμ). As the absorption at 546 mμ is mainly due to the phycobilins and chlorophyll *a*, it follows that quanta absorbed by the phycobilins excite chlorophyll *a* molecules to a stronger fluorescence than quanta absorbed by chlorophyll *a* itself. This surprisingly high yield of chlorophyll *a* fluorescence for light absorbed by the phycobilins, as compared with the yield for light absorbed by chlorophyll *a*, was also found—but still more pronounced—in the other species of blue and red algæ investigated.

From these observations it may be concluded, not only that chlorophyll *a* occurs in these cells in two different modifications, differing in fluorescence yield, but also that energy is transferred from the phycobilins to the highly fluorescent part of chlorophyll *a*, probably with high efficiency, and that consequently energy is not, or only to a slight degree, transferred to the weakly fluorescent chlorophyll *a* molecules. The weak fluorescence of these molecules in *Porphyra* may be due to transfer of energy to the above-mentioned unknown pigment, since its fluorescence is particularly strong (Fig. 2a) for the wave-lengths of incident light for which chlorophyll *a* fluorescence is comparatively low. The following observations support this view. By preliminary spectral and chromatographical investigations of *Porphyra* extracts carried out by F. van de Veerdonk in this Laboratory, a pigment was found—there are indications that it is chlorophyll *d*—of which the absorption was only about one-thousandth of that of chlorophyll *a* at the respective maxima of absorption. If we assume that this pigment occurs in *Porphyra* in the same ratio to chlorophyll *a* as in the extracts, its absorption is too small to be responsible for the strong fluorescence found. Therefore this fluorescence can only be due to energy-transfer from another pigment.

Energy transfer was also established in the red algæ from phycoerythrin to phycocyanin with an efficiency of probably more than 80 per cent in *Porphyridium cruentum*, and also from phycocyanin to chlorophyll *a* with about the same efficiency as from phycoerythrin. In these experiments, the wave-lengths of incident light exciting the fluorescence were: 546 mμ, mainly absorbed by phycoerythrin, and 600 mμ, mainly absorbed by phycocyanin.

Prof. C. S. French, working with *Porphyridium* at about the same time, kindly sent me action spectra, for incident light in the region 400–550 mμ, for the fluorescence of chlorophyll *a*, phycoerythrin, and phycocyanin. The action spectrum for chlorophyll *a* fluorescence demonstrates in an elegant way the low yield which occurs in the region in which chlorophyll *a* is mainly absorbing, as compared with the region in which phycoerythrin is mainly absorbing. The action spectra suggest, as Prof. French remarks, that light energy is transferred from phycoerythrin via phycocyanin to chlorophyll *a*. Hence our results seem to be in good accordance with his.

Light absorbed by the phycobilins proved to be more active in photosynthesis than light absorbed by chlorophyll *a*, as was previously established by Haxo and Blinks[4] for other species of red and blue algæ. Owing to experimental difficulties, hitherto we could only establish qualitatively the parallelism between the yield of chlorophyll *a* fluorescence and photosynthesis in red and blue algæ. Considering the position in other groups of organisms already described, we put forward the following picture of the two paths of energy transfer in red algæ:

(1) Phycoerythrin → phycocyanin → chlorophyll *a* → photosynthesis
↘ ↘ ↘
fluorescence fluorescence fluorescence and other energy losses.

(2) Weakly fluorescent chlorophyll *a* → unknown pigment →
↘ fluorescence
heat and other energy losses and other energy losses.

In the blue alga *Oscillatoria* the path of energy transfer was found to be the same, the only difference being that phycoerythrin is lacking. It should be emphasized, however, that in *Porphyra* the fluorescence of the unknown pigment is more pronounced than in the other species of red and blue algæ; so the energy transfer from the weakly fluorescent part of the chlorophyll *a* to this pigment is only assumed on grounds of analogy.

The transfer of electronic excitation energy between pigment molecules as reported above probably takes place through inductive resonance between the excited molecules and the molecules in the ground-state, a theory for which Förster[5] has given a quantum-mechanical treatment, with the aid of which the probability of energy transfer can be calculated from experimental data. Estimations, based on Förster's considerations, are in accordance with, or at least do not contradict, the results recorded above.

Summarizing, we may say that the evidence obtained is in favour of the view that, in algæ, light energy absorbed by a pigment, active in photosynthesis, is transferred to the 'chemical' part of photosynthesis only via chlorophyll *a*, and in purple bacteria only via bacteriochlorophyll *B* 890.

A detailed report of this and related work will be published elsewhere.

This investigation has been made possible by a grant from the Netherlands Organization for Pure Research (Z.W.O.) and was carried out under the direction of Prof. A. J. Kluyver (Delft) and Prof. J. M. W. Milatz (Utrecht). [May 9.

CONFIGURATION OF POLYPEPTIDE CHAINS

By PROF. LINUS PAULING, For.Mem.R.S.,
AND
PROF. ROBERT B. COREY

Gates and Crellin Laboratories of Chemistry, California Institute of Technology, Pasadena

WE have recently formulated a number of configurations of polypeptide chains that differ from all those previously discussed in that they conform rigorously to the structural principles that have been set up on the basis of the precise X-ray studies of crystals of amino-acids, simple peptides, and related substances that have been made in our Laboratories during the past fifteen years[1-4,8,9]. In the proposed configurations, the interatomic distances and bond angles have the values found experimentally, the amide groups are planar, and hydrogen bonds N—H. . . O are formed with the N—O distance 2·8 A. and with the oxygen atom close to the N—H axis. Agreement in dimensions of units of structure and in observed and calculated intensities of X-ray diffraction maxima has provided strong evidence that these configurations are present in various synthetic polypeptides[4] and fibrous proteins[5-8], and also in hæmoglobin[9].

Perutz has recently suggested[10] a way of testing for the presence of our 3·7-residue helix, which he describes as "a simple and decisive criterion in the X-ray diffraction pattern". In the 3·7-residue helix (which we call the α-helix) there are approximately 3·7 residues per turn of the helix, which has a pitch of about 5·55 A., and thus the axial length per residue is 1·5 A. Perutz has pointed out that the form factor for the helix would show a strong maximum in the meridional direction at the spacing 1·5 A., and that accordingly synthetic polypeptides and proteins with this helical structure would be expected to produce a diffraction maximum at the spacing 1·5 A., if the specimen be suitably oriented. He found that the reflexion is given by poly-γ-benzyl-L-glutamate, hair, and porcupine quill-tip, but not by hair stretched to the β-form. He concluded that the "presence of this reflexion does not in itself prove the correctness of Pauling and Corey's structure, but taken in conjunction with the favourable agreement of observed and calculated intensities of other reflexions already obtained by these authors, it leaves little doubt about their structure being right". It should be mentioned that we had previously mentioned the existence and significance of the 1·5-A. reflexion, in the following words (ref. 7): "We would expect that side chains of different kinds on the α helix would repeat after an integral number of residues, corresponding to an integral multiple of the residue length along the helix axis, about 1·53 A, and that accordingly those orders of basal plane reflection for which the spacing approximated closely to certain multiples of 1·53 A. would be enhanced in intensity. It is in fact found that about 80 per cent of the meridional reflections are of this type; for both Venus clam muscle and porcupine quill they are multiples of 1·51 A. The reflections at 1·49 A, 3·05 A, 4·50 A, and 6·19 A for porcupine quill, which represent the first four orders of enhancement, are the strongest features of the wide-angle meridional pattern, except for the 5·2-A arc."

Perutz also looked for the 1·5-A. reflexion on X-ray photographs of feather rachis keratin, for which we suggested a structure involving 3·7-residue helixes as well as pleated sheets of extended chains[8], and he states: "Prolonged exposure of seagull's feather rachis set at the appropriate Bragg angle revealed no trace of such a reflexion, which shows that the structure proposed by Pauling and Corey must be wrong". (We may add that we have recently discovered a type of pleated sheet differing somewhat from that described in our earlier papers; this new pleated sheet, with alternate chains reversed in direction, might be present in feather rachis keratin and other proteins, instead of the polar pleated sheet.)

We agree with Perutz that the 1·5-A. reflexion is an important criterion for the 3·7-residue helix, but our assessment of the significance of the absence of this reflexion differs from that of Perutz. We agree with him that the presence of the reflexion does not in itself rigorously prove the presence of the 3·7-residue helix, but that a strong reflexion in the right position relative to the fibre axis direction and with spacing in the range 1·46–1·55 A. is to be taken as very strong evidence of the presence of the α-helix. On the other hand, Perutz, as shown by his statement about feather rachis quoted above, has assumed that the absence of such a reflexion rigorously eliminates the α-helix from consideration. This is not true. For example, a protein or synthetic polypeptide might have a structure involving α-helixes packed together in such a way that half the helixes are displaced along the fibre axis relative to the other half by an odd multiple of 0·75 A. In this case the radiation scattered by one chain in the direction giving rise to the 1·5-A. reflexion would be exactly out of phase with the radiation scattered by a neighbouring chain, and interference would result which would cause the intensity of this reflexion to be zero. We hence conclude that the presence of the 1·5-A. reflexion is to be taken as strong evidence of the presence of polypeptide chains with the 3·7-residue helical configuration, but that the absence of this reflexion is not to be taken as strong evidence of the absence of the 3·7-residue configuration; it indicates either that these helixes are not present, or that they are present but are arranged in such a way as to produce strong inter-chain interference for this reflexion.

Let us consider as an example the crystalline synthetic polypeptide poly-γ-benzyl-L-glutamate, which we have described[4], on the basis of data published by Bamford, Hanby and Happey[11], as having a monoclinic (pseudo-orthorhombic) structure involving two polypeptide chains per unit, these chains having the 3·7-residue configuration, with eleven residues in three turns. The two chains in the unit appear to be related by a two-fold axis or a two-fold screw axis. If they were related by a two-fold axis the 1·5-A. reflexion would be expected to appear. If, on the other hand, they were related by the two-fold screw axis the two chains would be displaced along the direction of the fibre axis relative to one another by one-half the identity distance, that is, by one-half the distance occupied by eleven residues, and hence by an odd multiple (eleven) of 0·75 A.; the structure factor for the 1·5-A. reflexion (the reflexion 0.11.0 from the unit with fibre axis length b_0 = 17·3 A.) would be 0, and this reflexion would not be observed. The fact that Perutz has observed this reflexion for poly-γ-benzyl-L-glutamate shows that the two chains in the unit are not related by a two-fold screw axis.

Feather rachis keratin is similar, in that the structure which we have proposed for this protein involves two helical chains with the 3·7-residue configuration per unit of structure. We point out that there is a reasonable probability that the two α-helixes are displaced relative to one another by 0·75 A. or an odd multiple of this distance, which would lead to zero intensity for the 1·5-A. reflexion, and that accordingly Perutz's statement that "the structure proposed by Pauling and Corey must be wrong" is not justified. As to the structure itself, we may mention that we have proposed it for feather rachis keratin with some reserve, whereas our assignment of the 3·7-residue helix to the synthetic polypeptides poly-γ-methyl-L-glutamate and poly-γ-benzyl-L-glutamate and to α-keratin, α-myosin and related proteins, as well as to the rods discovered by Perutz and his co-workers in the hæmoglobin molecule[12,13], was made with much confidence, as was also our assignment of the three-chain helical structure to the fibrous proteins of the collagen–gelatin group. Our comparison of calculated and observed intensities of equatorial X-ray reflexions of feather rachis keratin provides some support for our proposed structure, but the support is far from conclusive. The statement by Ambrose and Elliott[14] that the infra-red spectrum of feather rachis indicates the presence of hydrogen bonds oriented parallel to the fibre axis as well as laterally also provides some support for the proposed structure, inasmuch as the α-helices involve parallel hydrogen bonds, those for the pleated sheet being lateral. Perutz's failure to observe the 1·5-A. reflexion does not eliminate this structure from consideration.

Polypeptide Chains in Muscle

In a recent paper on the configuration of polypeptide chains in keratin, myosin and related proteins[1], we have discussed a mechanism of the contraction of muscle, involving the conversion of the contractile protein from a pleated sheet of nearly completely extended polypeptide chains to a double row of 3·7-residual helixes. Through oversight we omitted to discuss the apparent incompatibility of our proposal with the X-ray data of Astbury and Dickinson[2], who reported a number of years ago that both extended and contracted muscle give X-ray photographs of the α-keratin type. Our attention has been directed to the oversight by several correspondents, and by a note by Huxley and Perutz[3], who have found that both extended and contracted dried frog sartorius muscle show the 1·5-A. reflexion characteristic of the 3·7-residue helix, and proposed by Perutz[4] as a criterion for the presence of this helix.

There are several different proteins present in muscle, and we think that it is likely that the protein which makes the greatest contribution to the X-ray diffraction pattern is not the one which undergoes significant structural change during the process of contraction. We suggest that the structural units 100 to 200 A. wide and 200 or 300 A. long, indicated by electron micrography to be attached together in a muscle fibril, consist of boxes made of α-keratin (and perhaps also in part of collagen), within each of which there are strung (in the extended fibril) pleated sheets of the contractile protein between the two ends connecting the box with the adjacent boxes in the fibril. We think it likely that the pleated sheets of contractile protein are not packed together in the way that they are in dried β-keratin or in silk fibroin, but are instead separated from one another by layers of solution which may be 50 A. thick, this separation permitting the easy access of solute molecules to the contractile protein. With such an arrangement of pleated sheets the characteristic β-keratin X-ray pattern would not be observed; the relative positions of pleated sheets so widely separated from one another would probably be sufficiently random to cause the aggregate to give rise only to a diffuse diffraction pattern, not much different from the molecular form factor for a single pleated sheet. In the extended muscle, the non-contractile α-keratin oriented parallel to the fibre axis of the muscle would give rise to the X-ray pattern reported by Astbury and Dickinson and by Huxley and Perutz. On contraction of the muscle the pleated sheets of contractile protein would be converted, according to our suggestion, into α-helixes, which would be well oriented with respect to the fibre axis of the muscle, whereas the non-contractile protein of the α-keratin type would become somewhat disoriented, as a result of the shortening of the structural unit of which, we postulate, it forms the framework. This structure could thus also account for the X-ray observations of Astbury and Dickinson and of Huxley and Perutz on contracted muscle.

We have proposed this mechanism of muscle contraction as a reasonable one, which is compatible with our present knowledge of the structural chemistry of polypeptide chains, and which accounts for the usually observed extent of contraction of muscle, namely, about 55 per cent. Although, as shown by the preceding discussion, the interpretation of the X-ray pattern will not be simple, a very thorough X-ray investigation might reveal the structure of the contractile protein as well as of the non-contractile protein in muscle. HIGH-POWER PHOTO-FLASH TUBES

By PROF. M. LAPORTE
Institut du Radium, Paris, 5e

IT is of very great advantage to be able to extend to cinematography, involving ultra-rapid exposures (less than 10^{-4} sec. duration) repeated at the requisite frequency over a long working time, the type of flash-tube which hitherto has been limited to use in simple photography with single exposures or with exposures taken at long intervals. This extension, however, presents entirely new problems in regard to the construction of such tubes. When flashes, each dissipating energy $W = \frac{1}{2}CV^2$ (energy of a condenser discharge), are repeated at the frequency n per sec., the average power dissipated over the working time t of the tubes is $\frac{1}{2}nCV^2$ watts. Flash tubes as at present constructed dissipate powers of less than 20 watts; for example, those giving a maximum of one flash of 100 joules every 5 sec.

We have made some progress in developing high-power tubes, which will operate, for example, at some hundreds of watts for a long working time, or at some kilowatts over a period of a few seconds. The following are the main principles of the design:

(1) The general dimensions, particularly the tube cross-section, are very large in order to permit adequate cooling.

(2) Instead of using internal electrodes, the electrodes form part of the envelope of the tube. The Kovar electrodes are joined to the glass (Moly glass) forming the rest of the tube by means of a gas-tight solder seal. The external surface of the electrodes is cooled by direct contact with the outside air; the cooling may be improved by the use of fins, or by the circulation of compressed air or water.

(3) When the tubes are used as optical sources, it is nearly always necessary to locate the light source in some definite position. This result is obtained by means of an axial canalizing tube (Fig. 1) of small section. This tube is made of quartz because of the high temperatures it has to withstand; and its diameter, of a few millimetres, is chosen so that the current density may attain values corresponding to the maximum light efficiency. In order that the discharge should pass only through this canalizing tube and not through the annular space between it and the envelope, the canalizing tube is extended by two bell-shaped ends B_1 and B_2 inside which each electrode projects towards the inside of the tube. This arrangement, which makes the discharge path through the canalizing tube shorter than any path passing through the annular space, was found to be completely efficient.

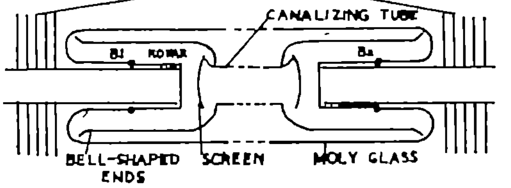

Fig 1

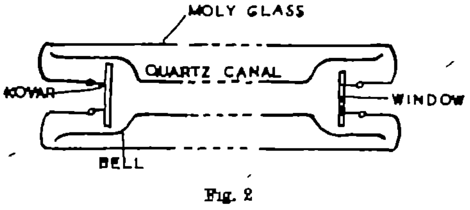

Fig. 2

(4) Intense pulverization of the cathode occurs in these high-power tubes, so producing an opaque deposit on the walls of the canalizing tube, which should be kept transparent. Owing to the fact that the metallic particles shot off from the cathode travel in straight lines, the canalizing tube can be kept transparent by placing a screen between it and the cathode, or by bending the tube at the cathode end.

Figs. 1 and 2 show two models of high-power flash-tubes which have been constructed in accordance with the above principles. That of Fig. 1 is used to make moving pictures, and operates for prolonged periods with an input power of 500 watts at the rate of 50 flashes/sec. (two flashes for one image). In the other model (Fig. 2) the extra high brilliance of the emitting tube at its end can be utilized, and in this case the cylindrical electrodes are sealed by Moly glass soldered to the metal by high-frequency heating[1]. This tube has made possible, for the first time, cinematography of living non-stained preparations with a phase-contrast microscope. The energy of a flash is about 10 joules, so that the tube must operate with an input of 1 kilowatt for a series of exposures at the rate of 100 images per sec.[2].

LEARNING ABILITIES OF BIRDS

A COMPREHENSIVE and meritorious survey of existing knowledge of the learning abilities of birds and their relation to the theory of instinctive behaviour has been set out in two recent articles by W. H. Thorpe (*Ibis*, 93, Nos. 1 and 2; January and April 1951). It is pointed out that the concepts of instinct and of learning are intimately related as complementary aspects of total behaviour, and that one cannot be understood without the other. Besides the definitions necessary for the description of instinctive behaviour and of learning itself, Thorpe also suggests definitions for certain other terms like reflex, kinesis, and taxis which are necessary for the full description of behaviour. The following is a summary of Thorpe's main conclusions.

Habituation is considered to be, in many respects, the simplest type of learning, and is one which is almost universal in animals. It is shown to be of vital importance in the process of adapting behaviour to generalized environmental stimuli (for example, sudden sounds, shadows and movements) which may be precursors of danger, but which experience has, in fact, shown to be harmless or of no significance. Habituation is thus caused by some stimulus or situation which puts the animal into a given mood but fails to lead to the release of a particular consummatory act. The more closely linked a stimulus situation (sign stimulus) is with a specific instinctive act, the less likely it is to be the subject of habituation.

The classical conditioned reflex is shown to be an artificially isolated part of a whole learning process and is only intelligible biologically as part of such a process. As with habituation, it is primarily one of the methods by which innate receptory correlates of the less specific kinds are elaborated to fit the environmental situation more exactly.

Trial-and-error learning incorporates an active appetitive behaviour which constitutes the process of trial and is characterized by the retroactive action of the influence exerted by the reward. Trial-and-error learning is shown to be of immense importance in the development of bird behaviour, particularly on the effector side, in the acquisition of skill involved in the perfection of elaborate behaviour patterns, such as flight, nest-building and escaping from enemies. On the receptor side of such behaviour the conditioning element in trial-and-error learning leads to modification of the configuration of stimuli to which the animal is responding. Trial-and-error learning also serves to account for many examples of learning with puzzle-boxes and mazes. The learning function of play in improving skill is considered as a phase and is more prevalent in young birds than is usually thought. The danger of confusing maturation of an innate behaviour pattern with improvement due to trial-and-error learning is stressed.

Under this head of insight learning, Thorpe discusses the type of exploratory learning now known as latent learning, and its significance in the establishment of territory; tool using and detour behaviour are also possible examples of insight learning. In an analysis of recent work on the number concept in birds, Thorpe suggests that Kohler's conclusions that certain birds show two pre-linguistic faculties, (1) simultaneous and (2) successive, *unnamed* number sense, little, if at all, inferior to that of man, must be accepted as proved. The essential difference, therefore, between the number concept of animals and men is that only the latter have, in addition, the ability to deal with 'named' numbers. The significance of visual illusion experiments for the theory of insight learning is also considered, as are some other learning abilities suggestive of insight.

Analysis of the imitative abilities of birds suggests that a distinction must be made between social facilitation, local enhancement and true imitation. The first two play an important part in bird life, but the evidence for true imitation is at present very slender; vocal 'imitation' is not considered necessarily to involve imitation in the true sense.

Discussing imprinting as an innate disposition to learn in a particular direction and in a particular restricted period, it is believed that, once accomplished, this type of learning is particularly difficult to eradicate and is significant in understanding the theory of instinctive behaviour, and especially of the innate releasive mechanism. The important evidence supplied by pathological imperfections in imprinting is examined while the perceptory side of song learning is considered as a special case of imprinting.

Some learning abilities are of doubtful significance, the most important of these being the ability to recognize individuals. The subject of tameness is also discussed, and, in Thorpe's view, genetic tameness and wildness are undoubted realities. No evidence is found for an inherited recognition of man as an enemy, but it is shown that a tendency to general wariness readily becomes attached to man, but can be overcome by a variety of learning processes.

The memory powers of birds are also considered; instances of memory for individuals extending for periods of a year or more are well authenticated; and it is possible that memory for territory is often still more enduring.

MANAGEMENT PROBLEMS AND LOCAL GOVERNMENT

IN the most recent occasional paper of the British Institute of Management, Mr. J. E. MacColl suggests that, though latent for many years, there is a crisis in local government which has been made more acute by the stresses of post-war reconstruction.

Because of this stress, there has been a trend of functions from small authorities to large, and from large authorities to the central government. From a purely administrative point of view "large local authorities are more likely to be effective instruments than small ones. For many purposes the central government may be the most effective of the lot." But in our desire to produce maximum administrative effectiveness, care must be taken not to overthrow democracy itself. Mr. MacColl states that highly efficient local government departments are not necessarily satisfactory, and humanity, imagination and sensitiveness to local feeling are no less important than costs per head. People should not feel that their communal services are supplied from above regardless of their likes and dislikes, the ultimate test in a local democracy being whether the citizens find their town a pleasant place to live in and whether they feel responsible for what is done in their name.

Nevertheless, local government must be assessed by efficient criteria, and, in the first place, it must be acknowledged that much inefficiency has nothing at all to do with the limitations set by democratic control. In the second place, it is desirable to know what, in fact, are the costs of democracy. It is dangerously easy for councillors to ask for this return or that without any idea of what it really means in terms of extra cost. Mr. MacColl also discusses the lack of any adequate check on the number of staff in local government services. Although local government officers and especially senior officers work hard, much of their work could either be avoided or lightened. Each extension of intensification of activity leads to a demand for more staff, who really are needed unless or until somebody starts at the beginning to recast the whole administrative scheme.

As the amount of work a local authority is called upon to do increases, more and more staff are employed, extra office space taken over and a rich variety of forms designed. There is pressure from committees to speed up output of houses or to open new branches of the public library, pressure occasionally punctuated by panic when increases of rates threaten. The process goes on without anyone asking whether the load could be carried more efficiently or shared more evenly; perhaps without anyone having a clear idea how to set about finding this out. These difficulties are accentuated by excessive departmentalization and the absence of a general manager. Although it may be disturbing to those with orthodox views of British local government, there may be need for a hybrid political administrator to make the kind of contribution of the burgomaster or the American mayor.

Mr. MacColl also discusses the kind of men and women who are needed in local government service, and the relationships which should exist between the paid officers and the lay councillors. One of the crucial issues to be decided is whether it is more important to have highly trained and expensive administrators, or men and women who understand the peculiarities and idiosyncrasies of their own locality.

Blue Sun and Moon

ALTHOUGH the blue sun and moon are noteworthy phenomena, the physical origin of the colour does not appear to be well known. While, therefore, the following explanation is presumably neither novel nor complete, it may interest those who wish for "the vivid colouring of a physical illustration".

The cause of the sun appearing red has long been known to be due to the preferential scattering of blue light relative to red by dust particles and to small-scale fluctuations in refractive index in the atmosphere. Rayleigh showed that for particles of any given size much smaller than the wave-length, the scattering of radiation is inversely proportional to the fourth power of the wave-length; thus, for particles of less than 0·1 micron in diameter, light of wave-length 4000 A. would be scattered nine times more effectively than light of wave-length 7000 A. For the sun to appear blue, the relative magnitudes of scattering must be opposite to those which the Rayleigh theory predicts. This opposite condition can arise when the particles do not obey Rayleigh's criterion of being small compared with the wave-length.

The theory of scattering of electromagnetic radiation by spherical particles above the Rayleigh limit was first worked out by Mie[1], and extensive computations have since been made, by several workers, of the scattering under different conditions. Fig. 1 shows, for example, a curve derived by a method due to van de Hulst[2] of the variation with wave-length of the 'extinction' produced by a dielectric sphere. 'Extinction' is defined as the ratio of the effective cross-section over which radiation is stopped or diverted by a body to the geometrical cross-section which the body presents to the incident radiation.

A qualitative explanation of the main features of the curve can be given without going into detailed theory, and for this purpose the curve may be divided into three regions. The first (*A*) is the Rayleigh region, where the particle radius *r* is small compared with the wave-length λ, and the curve from the origin obeys the fourth-power law. The third region (*C*) is where the sphere is much larger than the wave-length; here it can be shown that not only does the sphere divert by refraction or reflexion all the radiation that falls upon it, but that it also diverts an equal amount by diffraction in the region around its edges. This fact, of which Walton[3], for example, gives a simple explanation, produces an extinction value of 2 instead of 1; this value is constant for all wave-lengths small compared with the sphere.

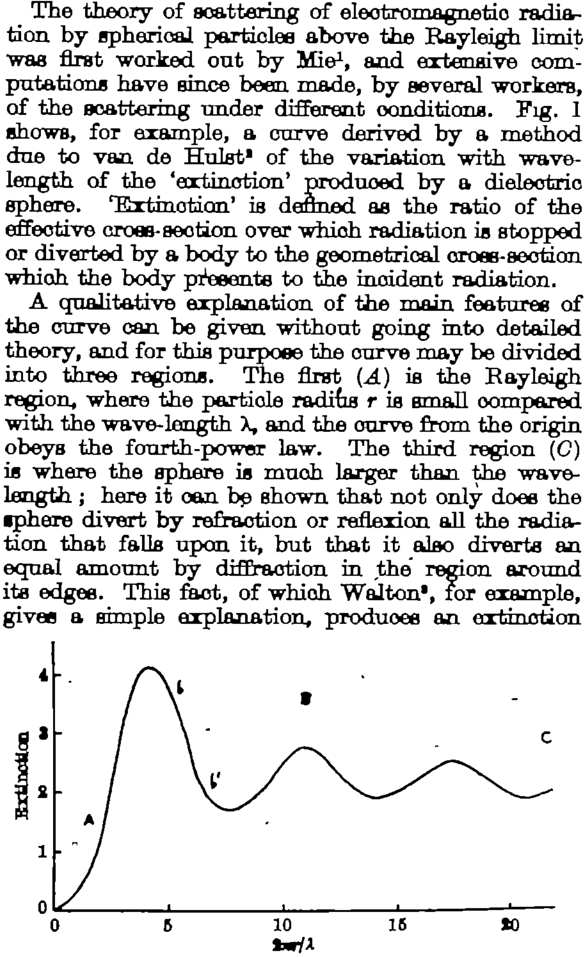

Fig. 1. Theoretical extinction of radiation of wave-length λ produced by a dielectric sphere of radius *r*, and refractive index 1·5

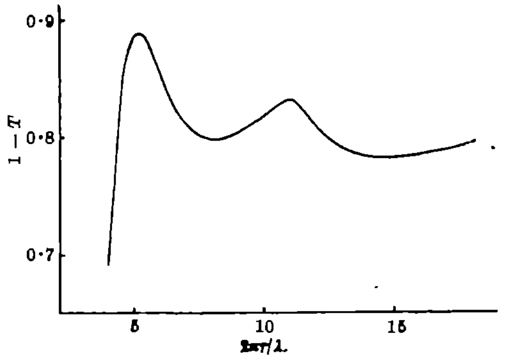

Fig. 2. Observed variation of (1 − transmission) with $2\pi r/\lambda$ for glass spheres of radius 3·5 microns and refractive index 1·5

In the intermediate region *B*, the Mie theory shows several peaks. These again could be expected qualitatively, since the particle size is here comparable with the wave-length, and resonances might occur, the fundamental being presumably the strongest. It is well known that in resonance the resonator effectively absorbs and re-emits radiation from a cross-section which may be several times its geometrical cross-section, and since the re-emission occurs in all directions, nearly all this radiation is effectively diverted from its original direction. The effective cross-section might therefore be expected to reach maxima at a series of values corresponding to the resonances, giving the form of curve predicted by the Mie theory. This form of curve is confirmed by observations on the scattering of infra-red radiation by small glass spheres[4]. Fig. 2 shows a typical observed curve for glass spheres of diameter 7 microns. The transmission of a screen consisting of a monolayer of many separate particles was actually observed; and (1 — transmission), which should be directly proportional to the extinction produced by a single particle, was plotted against $2\pi r/\lambda$.

The form of the intermediate region in Fig. 1 will account for the blue sun. Wherever the extinction curve is rising, light of longer wave-length will be scattered less than that of shorter wave-length, as in Rayleigh scattering; but wherever the extinction curve is falling, the opposite will be true. In order, therefore, for red light from the sun to be scattered more than blue light, the atmosphere must contain a large number of particles of greater size than usual, and those particles must be grouped in a narrow size-range, corresponding to such a region as *bb'*. A typical diameter would be 1·7 microns for particles of refractive index 1·3, and 1 micron for refractive index 1·5. Such conditions occur only rarely and require either a large-scale liberation of uniform particles of suitable size into the atmosphere, or (more probably) the separation by some atmospheric process of particles in the suitable size-range from a cloud of particles of random size. A corollary to the blue sun is that the sky might at the same time appear pink instead of blue.

An Accurate Determination of the Positions of Four Radio Stars

The use of an interferometer aerial system on a wave-length of 3·7 m. to measure the positions of a number of radio stars has already been described[1]. The present communication contains the results of recent more accurate determinations of the positions of four intense radio stars with this interferometer, together with results for the same stars obtained by using another interferometer the individual aerials of which employ parabolic reflectors. This latter interferometer has been used at wave-lengths of 3·7 m. and 1·4 m.

With the new interferometer, it is possible to determine the 'collimation error' either by the interchange of the individual interferometer aerial elements, or by observations of both upper and lower culmination of the circumpolar star 23·01 [1]. In addition, the electrical centres of the aerials are defined more precisely than those of the broadside arrays originally used at 3·7 m.

Declination has been determined from the periodicity of the record, as in the previous observations, and also by two new independent methods. In the first method the times of transit of the star across two 'collimation planes' displaced on either side of the axial plane of the interferometer are determined: the interval between these times is related to the declination. These displaced collimation planes are produced by increasing the electrical path to one or other of the aerials. In the second method, the time-interval between the transits at the upper and lower culminations of a circumpolar star provides a measure of the declination, since the axis of the interferometer is inclined at a considerable angle to the east–west line. The collimation error must here be determined by interchanging the interferometer aerials. A more detailed account of these and other methods of position-finding will be published elsewhere.

Table 1 gives the positions of the four stars, with their probable errors, as determined from the time of transit and the periodicity of the record obtained with the three interferometer systems. It also shows results obtained by the two new methods, which have been used at 1·4 m. Allowance has been made for atmospheric refraction. The co-ordinates refer to the epoch of 1950.

It has been pointed out[1] that, in addition to the instrumental errors, the position may be in error due to the radiation from other nearby weaker stars. It can be shown that, in the present observations, this factor is unlikely to cause an error greater than ½ sec. in the R.A. of the stars 19·01 and 23·01, or greater than about 2 sec. in the R.A. of the less-intense stars 05·01 and 12·01.

Table 1

Star	Constellation	Wave-length and method	Right Ascension	Declination
			h. m. s.	
05·01	Taurus	3·7 m., broadside	05 31 35 ±5	22° 05′ ±40′

A Search for Long-Period Variations in the Intensity of Radio Stars

Certain classes of visible star are characterized by well-marked variations of intensity; the period of these variations may be as short as a few hours, or as long as several hundred days. In this communication an account is given of an investigation which has been made to determine whether any of the known radio stars exhibit similar variations of intensity.

The present observations were made on a wave-length of 3·7 m. with an interferometer aerial which has already been described[1]. This system employs two fixed aerials, each of which has a large aperture in an east–west direction and a small aperture in a north–south direction; the interferometer is therefore receptive in a narrow strip which extends along the meridian from about declination + 10° to declination + 80°. Daily observations can therefore be made of radio stars situated throughout most of the northern hemisphere. The number of radio stars which can be distinguished is limited by confusion between the traces produced by adjacent stars and not by the random fluctuations on the record. Thus, although it is only possible to locate about fifty of the most intense radio stars, other sections of the record show well-defined periodic traces due to the simultaneous reception of the radiation from two or three weaker stars. It is not possible to deduce the absolute intensity or the accurate positions of these weaker sources; but by making a detailed comparison of the records obtained each day, it is possible to detect small variations in their intensity.

Observations have been made with this system nearly every day for more than eighteen months, although records representing about 15 per cent of the total observing time have had to be rejected from the present analysis owing to the occurrence of severe 'scintillation' caused by diffraction in ionospheric irregularities[2]. It was found that, of approximately a hundred radio stars examined, none showed any variation of intensity greater than 10 per cent; a more detailed analysis of some of the more intense ones suggested that their intensity was, in fact, constant to better than 5 per cent; but it is difficult, at this wave-length, to eliminate the effects of residual ionospheric irregularities for variations smaller than this.

It is therefore concluded that none of the radio stars observed varies by more than 0·1 magnitude with any period shorter than about 1,000 days; observations of the more intense stars suggest that their intensities may, in fact, be constant to within 0·05 magnitude.

This result is of interest not only for comparison with the behaviour of visible stars, but also in contrast to the marked day-to-day variations in the intensity of the metre-wave radiation from the sun.

This work forms part of a programme of research which is supported at the Cavendish Laboratory by the Department of Scientific and Industrial Research.

Nuclear Spin of Rubidium-86

THE nuclear spin I of rubidium-86 has been measured by the atomic beam method using magnetic resonance; a mass spectrometer was employed to select the correct isotope[1]. A pronounced resonance was obtained at a frequency of 2·36 Mc./sec. in a magnetic field of 4·22 gauss, which gives $I = 2$. This value is in agreement with the observed shape of the β-spectrum[2]. The hyperfine structure separation was found to be 3,900 ± 100 Mc./sec., which means a magnetic moment of 1·66 ± 0·4 nuclear magnetons. The results suggest that the magnetic moment is probably negative and it would then have a value of − 1·68 ± 0·01 nuclear magnetons. It is planned to extend the measurements to obtain a more accurate value of the magnetic moment and definitely establish its sign.

The rubidium-86 was prepared by the ^{88}Sr (d,α) ^{86}Rb reaction. I wish to thank the Physics Department of the University of Birmingham for carrying out this bombardment, and Dr. A. G. Maddock, of the Radiochemistry Laboratory, Cambridge, for the chemical separation of the rubidium-86.

Scattering of 146-MeV. Protons by Deuterons

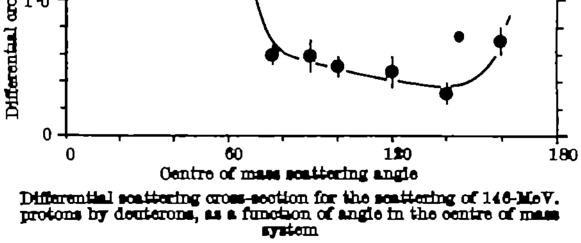
THE proton beam and the counting apparatus described in an earlier communication[1] have now been used for a study of elastic proton–deuteron scattering. The results are shown in the accompanying graph.

The scatterer was a rectangular strip of heavy water contained in a capsule made of thin aluminium sheet. Elastic proton–deuteron collisions were observed by detecting in coincidence both the scattered protons and the corresponding recoil deuterons. When the angle of scattering was less than 67° or greater than 85°, the geometry of the arrangement left no doubt as to which counter was detecting the protons in these events. Between these two angles it was not practicable to determine the cross-section except at 76°, where the recoil angles of the two particles are actually equal.

Various background effects were subtracted with the help of a second scatterer filled with normal water. Proton–proton collisions in the hydrogen content of the normal water were not counted, again because of the geometry of the arrangement. All background effects should have been unchanged by the substitution of normal for heavy water, with the exception of that due to inelastic proton–deuteron scattering followed by the detection of both protons. There are three final particles involved in this process, so that the recoil angles of the two protons are not uniquely connected. A consideration of the solid angle subtended by the counters suggested that this source of background could be neglected, and this conclusion was supported by an experiment in which the geometry of the detectors was varied.

The uncertainties shown in the graph are the statistical errors in the determination of the relative values at different angles; it is considered that systematic errors were small in comparison with these. The absolute cross-section was fixed by observing proton–proton scattering with the same apparatus, the cross-section for that process being taken[1] as 4·99 ± 0·31 millibarns. The absolute calibration of the proton–deuteron experiment is subject to an overall standard deviation of 7·8 per cent.

It is hoped to improve the accuracy of these results and later to obtain some information about neutron–deuteron scattering at the same energy. A



Differential scattering cross-section for the scattering of 146-MeV. protons by deuterons, as a function of angle in the centre of mass system comparison of the two effects should show whether, apart from the Coulomb repulsion, the proton-proton and the neutron–neutron interactions are the same at high energies. The recently published results of Stern and Bloom[2] on the scattering of 190-MeV. deuterons by protons (equivalent to the scattering of protons of approximately 95 MeV. by deuterons) are of great interest from this point of view. If their results are integrated over all angles, an elastic cross-section of roughly 24 millibarns is found. W. M. Powell[3], on the other hand, has observed an elastic neutron–deuteron cross-section of 48 millibarns at 90 MeV. neutron energy.

The experiment reported here was greatly assisted by the co-operation of Mr. A. O. Edmunds and the cyclotron crew. One of us (G. H. S.) is a member of the staff of the South African Council for Scientific and Industrial Research.

Raman and Infra-Red Spectra of Germanium Tetrafluoride

The Raman spectrum of gaseous germanium tetrafluoride at 1·8 atm. has been investigated with mercury arc excitation, and two lines have been observed. One is excited by λ 4358 and the other by λ 4046 A., the measured Δν-values being 737·1 and 738·4 cm.$^{-1}$ respectively. This shift may with confidence be identified with the symmetrical breathing frequency of the tetrahedral GeF$_4$ molecule, to which we assign the value $\nu_1 = 738 \pm 2$ cm.$^{-1}$.

We have also observed the infra-red absorption spectrum of gaseous germanium tetrafluoride. This shows several bands, the most intense of which lies at 800 cm.$^{-1}$ and probably corresponds to ν_3.

Further details of the spectra will be published later.

Runs in a Sequence of Observations

In previous communications[1-4] one of us (P. V. K. I.) has discussed a number of distributions arising from m observations belonging to k groups arranged at random on a line. When all the observations are different, m is equal to k, and for this case Kermack and McKendrick[5], and Levene and Wolfowitz[6] have considered the distribution of the number of runs 'up' and 'down'. A run 'up' or 'down' is a succession of observations in ascending or descending order. Kendall[7] has dealt with the same problem by considering the number of 'troughs' and 'peaks'. When m is greater than k, the sequence of observations will have three kinds of runs, namely, ascending, descending and stationary. This note gives the difference equation satisfied by the probability generating function and the first two moments for the distribution of the total number of *junctions* for a sequence of m observations with fixed probabilities $p_1, p_2 \ldots p_k$, a junction being the meeting point between two runs 'up', 'down' or stationary. It may be noted that the total number of runs is equal to the total number of junctions increased by unity.

The difference equation reduces to a $k \times k$ determinant as shown below:

$$\begin{vmatrix} \theta_1 & \psi_{10} & \psi_{11} & \psi_{12} & \cdot & \psi_{1,k-2} \\ \lambda_{20} & \theta_2 & \psi_{20} & \psi_{21} & \cdot & \psi_{2,k-3} \\ \lambda_{31} & \lambda_{30} & \theta_3 & \psi_{30} & \cdot & \psi_{3,k-4} \\ \lambda_{42} & \lambda_{41} & \lambda_{40} & \theta_4 & \cdot & \psi_{4,k-5} \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \lambda_{k,k-2} & \lambda_{k,k-3} & \lambda_{k,k-4} & \lambda_{k,k-5} & \cdot & \theta_k \end{vmatrix} \varphi(m-2) = 0$$

where $\theta_r = E^2 - p_r(p_r + q_r t)$; $\psi_{rs} = -p_r[p_{r+1} + p_{r+2} + \ldots + p_{r+s} + (1 - p_{r+1} - p_{r+2} - \ldots - p_{r+s})t]$ $\lambda_{rs} = -p_r[p_{r-1} + p_{r-2} + \ldots + p_{r-s} + (1 - p_{r-1} - p_{r-2} - \ldots - p_{r-s})t]$; $p_r + q_r = 1$; E is the usual operator in finite difference and

$$\varphi(m) = p(m,0) + p(m,1)\,t + p(m,2)\,t^2 + \ldots,$$

$p(m,r)$ being the probability for r junctions in m observations.

The first two moments are:

$$\mu'_1 = (n-2)\,\{4\Sigma p_r p_s p_t + 3\Sigma p_r p_s(p_r+p_s)\} = (n-2)\,P_1(3),$$

$$\mu_2 = \mu'_1 + 2\,(n-3)\,\{10\Sigma p_r p_s p_t p_u + 8\Sigma p_r p_s p_t\,(p_r + p_s + p_t) + 6\Sigma p_r^2 p_s^2 + 2\Sigma p_r p_s\,(p_r^2+p_s^2)\} + 2(n-4)\{54\Sigma p_r p_s p_t p_u p_v + 34\Sigma p_r p_s p_t p_u(p_r+p_s+p_t+p_u) + 2\Sigma p_r p_s p_t p_u(p_s+p_t) + 22\Sigma p_r p_s p_t(p_r p_s+p_s p_t+p_r p_t) + \Sigma p_r p_s p_t(p_r p_s+p_s p_t) + 12\Sigma p_r p_s p_t(p_r^2+p_s^2+p_t^2) + 2\Sigma p_r p_s p_t(p_r^2+p_t^2) + 8\Sigma p_r^2 p_s^2(p_r + p_s) + \Sigma p_r p_s(p_r^3 + p_s^3)\} - (5m - 16)\,[P_1(3)]^2,$$

$$r > s > t > u > v.$$

The moments for the case when $n_1, n_2, \ldots n_k$ observations belong to k different groups are obtained by substituting

$$\frac{n_r^{(\alpha)}\, n_s^{(\beta)}\, n_t^{(\gamma)} \ldots}{n^{(\alpha+\beta+\gamma \cdots)}} \text{ for } p_r^\alpha\; p_s^\beta\; p_t^\gamma \ldots$$

in the moments about the *origin* for fixed p's.

The above moments have been obtained by extending the methods developed by one of us[3,4], by forming the frequencies for three, four and five observations for all possible combinations of equal and unequal observations.

It can be established from the difference equation that all the cumulants of the distribution are linear functions in m, and hence the distribution tends to the normal form as $m \to \infty$. Full details of this work will be published in the *Journal of the Indian Society of Agricultural Statistics*.

Metallic Oxides with the Structure of High-speed Steel Carbide

OXIDES isomorphous with the high-speed steel carbide Fe_3W_3C have been found to exist with the ideal composition Me_3Ti_3O, where Me is one of the transition metals manganese, iron, cobalt, nickel or copper (but *not* vanadium, chromium or zinc).

The best agreement between calculated and observed $p \mid F \mid^2$ values for powder photograph reflexions and the best space distribution in the cubic unit cell is obtained if the 112 atoms are placed in the following positions of the space group $O_h^7 - Fd3m$:

16 O in 16 : (*c*) 1/8, 1/8, 1/8 ;
16 *Me* in 16 : (*d*) 5/8, 5/8, 5/8 ;
32 *Me* in 32 : (*e*) *x*, *x*, *x* ; ($x = -0{\cdot}165$)
48 Ti in 48 : (*f*) *x*, 0, 0 ; ($x = 0{\cdot}185$)

Analysis of powder photographs taken with oxides of different compositions gives the probable lower and upper phase limits for the titanium content as Me_3Ti_3O and Me_2Ti_4O respectively. At the latter composition 16 titanium atoms and 16 *Me* atoms are randomly distributed in 32 : (*e*). In comparison, 16 iron atoms take up the positions of 16 tungsten atoms in 48 : (*f*) in high-speed steel carbide of the composition Fe_4W_2C. The following values for the length of the unit cube edge have been found:

Me	Titanium-poor limit	Titanium-rich limit
Mn	11·10 A.	11·28 A.
Fe	11·14	11·31
Co	11·16	11·32
Ni	11·18	11·37
Cu	11·24	11·44

All the new oxides have metallic properties. It is of interest that the titanium atoms, independent of the composition, are surrounded octahedrally by six oxygen atoms.

A detailed report will appear shortly elsewhere.

Source of Moulting Hormone in *Rhodnius*

THE immediate source of the hormone which induces moulting in the larvæ and pupæ of Lepidoptera is the prothoracic gland[1]. But this gland is itself activated by a secretion from neuro-secretory cells in the dorsum of the brain[2]. It has seemed probable for some time that a similar two-stage control of moulting might exist in other insects[3]; and recently it has been found by Possompès[4] that the lateral cells of the ring gland in the larvæ of Diptera are induced to secrete the pupation hormone by a factor liberated from the brain.

It has now been shown that the same sequence of events occurs in *Rhodnius*. Fourth-stage larvæ of *Rhodnius* decapitated at 24 hr. after feeding can be induced to moult by implanting into the abdomen the dorsal region of the brain from larvæ that have just passed the 'critical period'[5]. In the present series, this experiment succeeded in 80 per cent of cases. But if the recently fed larva is ligatured behind the mesothorax and the same implants are made into the isolated abdomen, this fails to moult. There were no positive results in twenty-three experiments.

Search in the thorax has revealed the presence of two strands of large cells, with enormous lobulated nuclei, deeply imbedded in the fat body and extending throughout the prothorax and mesothorax. These cells are abundantly supplied with tracheoles. They undergo a cycle of development in each moult, increasing greatly in size at the 'critical period', becoming small again at the end of the moulting stage. They break down and disappear in the adult within forty-eight hours after moulting.

If these cells are removed from a larva that has just passed the critical period and are implanted into the abdomen of a larva decapitated at 24 hr. after feeding, this is caused to moult (six positive in eighteen experiments). If they are implanted into recently fed larvæ ligatured through the metathorax, the isolated abdomen is likewise caused to moult (seven positive among thirteen survivors).

Similarly, the adult *Rhodnius* is not caused to moult by implantation of the brain; but moulting is induced if the thoracic gland from the moulting fifth-stage larva is implanted.

A corresponding gland has been found also in *Nepa*, where it likewise disappears in the adult insect.

Activation and the Correlation between Male and Female Elements in Fertilization

IN the course of investigations on the process of fertilization, immature rats, which had been allowed to mate, were killed shortly after induced ovulation. Thirty-six animals yielded 477 eggs in the early phase of fertilization. The correlation in the stages shown by the male and female elements in the living eggs was carefully examined with the aid of the phase-contrast microscope. The stages were classified as follows: for the male element, (*a*) sperm present in the perivitelline space, (*b*) sperm in the vitellus but with head unchanged, (*c*) sperm head changing, (*d*) male pronucleus forming; for the female element, (*a*) chromosomes in metaphase of second maturation division, (*b*) in anaphase, (*c*) in telophase, (*d*) polar body abstricted, (*e*) female pronucleus forming. The numbers of eggs showing these stages are recorded in the accompanying table.

Of the 108 eggs which contained sperms only in the perivitelline space, the great majority (103) displayed chromosomes arranged in metaphase. In the

CORRELATION BETWEEN MALE AND FEMALE ELEMENTS DURING EARLY STAGES OF FERTILIZATION IN 477 RAT EGGS

Female / Male	Chromosomes in metaphase	Chromosomes in anaphase	Chromosomes in telophase	Polar body formed	Pronucleus forming
Sperm in perivitelline space	103	1	1	3	
Sperm in vitellus, unchanged	4	8	6	1	
Sperm in vitellus, head changing		5	47	173	1
Pronucleus forming				47	77

remaining five eggs, however, the mitosis had proceeded and in three of them the polar body had been formed. These five eggs thus exhibited signs of activation although no sperm had yet entered the vitellus.

Only nineteen eggs were observed in which there was an unchanged sperm within the vitellus. The infrequency of the observations connotes the brevity of this state. Most (fifteen) of these eggs showed signs of activation, including one in which the second polar body was visible. In the remaining four eggs sperm entry probably occurred just before the eggs were obtained for study; but some delay of activation is here indicated.

In 226 eggs the head of the penetrating sperm showed distinct changes, and in the majority (173) the second polar body had been formed. Some eggs (47), however, had chromosomes still in the telophase condition. In this series also there were indications both of early activation (one egg) and delayed activation (five eggs).

Finally, 124 eggs were observed showing the early stages of formation of the male pronucleus. The larger proportion (77) of these showed also the early female pronucleus; but the remainder (47) carried egg chromosomes still in the form seen after polar body formation.

Another group of immature rats was killed at a later stage, between 16 and 26 hr. after ovulation. Among these were 57 animals which yielded 228 eggs showing the various stages involved in the reappearance of the chromosomes and the formation and division of the first segmentation spindle. In none of these eggs was there any indication of a lack of correspondence between the male and female elements.

From these observations the following conclusions are drawn. There is a fairly close correlation between the male and female elements in the early phase of fertilization of the rat's egg. While the sperm is in the perivitelline space, the egg chromosomes are nearly always in metaphase. After the sperm has entered the vitellus, but before it has undergone perceptible change, the egg chromosomes are mostly seen in anaphase or telophase. The mitosis evidently proceeds very shortly after sperm entry. Soon the sperm head shows changes in form, and by the time these have become distinct the polar body is abstricted. Nearly always the early form of the male pronucleus appears before the female (47 eggs had only the male pronucleus; only one egg had solely the female pronucleus).

Activation of the egg may occur before the sperm has entered the vitellus, though the sperm head may possibly have broken the continuity of the vitelline surface. On the other hand, activation may occasionally be a little delayed. For these reasons the correlation seen in the early stage of fertilization is incomplete. Later, however, a closer correspondence is observed and is especially evident at the stages immediately preceding segmentation. Apparently a co-ordinating influence in the egg becomes effective in the course of fertilization.

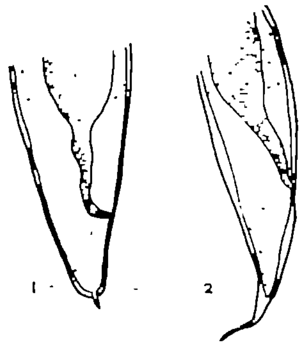
A New Species of *Nematodirus* in Sheep

Outbreaks of parasitic disease in lambs have occurred in the north of England during June and July 1951. Deaths have been associated with the presence of large numbers of nematodes of the genus *Nematodirus*. We are grateful to Mr. W. Lyle Stewart, who sent us the contents of the intestines of five lambs which had been sent to him for examination. About two million worms were received, and the collection was remarkable not only because of the large numbers but also because more than 90 per cent of the worms belonged to the genus *Nematodirus*. Examination showed that there were no *N. spathiger*, a large number of *N. filicollis* and a large number of a third species of *Nematodirus*. This last species cannot be referred to any known member of the genus, and it is proposed to name it *Nematodirus battus*. The description is as follows.

Nematodirus battus n.sp. Body attenuated anteriorly. Mouth surrounded by six papillæ. Cephalic cuticle dilated. *Male*: Length 10–13 mm., maximum diameter 0·12–0·13 mm. Bursa with two large lateral lobes; dorsal lobe small. Ventroventral and latero-ventral close and parallel; laterals arise from a common trunk, diverging in the distal half; postero-lateral and medio-lateral not parallel; externo-dorsal arises close to the base of the dorsal ray, which is doubled and has bidigitate extremities. Spicules filiform, 0·85–0·95 mm. long; tips united by a membrane; end bluntly pointed. Gubernaculum absent. *Female*: Length 17–22 mm., maximum diameter 0·16–0·22 mm.; vulva in the posterior third of the body. Tail pointed. Eggs large, 195 μ × 95 μ. Host: *Ovis aries*. Location: small intestine.

This species can be distinguished from others of the genus by the fact that the tail of the female is not truncate but finely pointed, and that the bursa of the male has the medio- and postero-laterals divergent and not parallel.



(1) *N. filicollis*, tail of female; (2) *N battus*, tail of female

A more detailed description will be given elsewhere; but the above description is provided to enable observations to be made during the present outbreak. This species can be most rapidly separated from *N. filicollis* and *N. spathiger* by examination of the tails of female worms (see Figs. 1 and 2), and it is hoped that other workers may contribute information on the distribution and biology of this worm.

Mytilicola intestinalis, Steuer, in the European Flat Oyster (*Ostrea edulis*)

While examining a sample of ninety-six two- and three-year-old oysters taken from the Penryn River, Cornwall, on June 20 to assess the incidence of Dutch shell disease[1], *Mytilicola intestinalis* was found in three of the oysters. As the main initial interest of the sample lay in the shells, the meats were being discarded without examination. About thirty oysters had been opened and the meats discarded when a slip of the knife resulted in the cutting of the visceral mass; *Mytilicola* was then observed. The remaining sixty-six oyster meats were examined as the oysters were opened; two were found to be infected, but small parasites may have been overlooked.

A further sample of fifty similar oysters was procured from Penryn on June 26. Two *Mytilicola* were found in one oyster. The percentage infection would thus appear to be of the order of 3 per cent.

The infestation was light, the largest number of parasites found in one host being three. The ten parasites found comprised eight females and two males. Two females carried external egg-sacs, another had well-developed internal gonads, and the remainder were immature.

Mussels in the district are heavily infected with *Mytilicola*; but they are not abundant on the grounds from which the oysters were taken.

On July 7 a similar sample of two and three year-old native oysters taken from Tollesbury North Channel, on the north side of the River Blackwater, Essex, was also found to be infected. It was not possible to examine the oysters with the care necessary to detect small parasites; but six oysters out of 111 yielded a total of seven large *Mytilicola*, including two females with external egg-sacs. The parasites lay in the excurrent limb of the intestine, some distance forward from the anus, and could not be seen until the visceral mass was cut. Mussels in the River Blackwater are known to be infected with *Mytilicola*, and the parasite has been established in the vicinity for several years.

So far as is known, these are the first records of the occurrence of this parasite in oysters, but *Mytilicola orientalis*, Mori, has been recorded from *Ostrea lurida* on the Pacific coast of America[2].

It has been shown[3] that heavy infestation with *Mytilicola* is associated with serious loss of condition in mussels. There is the possibility, therefore, that a similar loss of condition may occur in infected oysters. The very light infestation in areas where *Mytilicola* is well established suggests that the infection of oysters requires a special set of conditions which does not occur very frequently in Nature. It is to be noted, however, that the gonads of several of the parasites were mature, and the possibility that *Mytilicola intestinalis* may become adapted to life in oysters cannot be excluded.

The Leaf Scar as an Avenue of Infection for the Cherry Bacterial Canker Organism, *Pseudomonas mors-prunorum* Wormald

The development of branch cankers from previously infected fruiting spurs was noted by Wormald[1] in his original etiological study of the bacterial canker disease of cherry (*Ps. mors-prunorum*), and later by Webb[2], who concluded that most branch cankers originated in this way. Records made over the past two years during field observations on 5–12 year old cherries of several varieties have confirmed this view. Between 90 and 100 per cent of branch cankers examined, depending on the age and variety of the tree, were around the base of a dead spur. This association, together with the frequent occurrence of dead spurs with incipient cankers at the base and dead spurs without basal cankers, clearly indicated the sequence of infection.

As the fruiting spurs are thus primarily concerned in the initiation of the branch cankers, the mode of entrance of the pathogen into them is therefore highly relevant to the formulation of control measures. Most of the foliage is borne on these spurs, and Montgomery and Moore[3], who effected some control of the canker phase by the autumnal application of Bordeaux mixture sprays, suggested that the spurs become infected through the leaf scars during the autumnal leaf-fall period. This is the only time in the annual cycle of the disease when the condition of winter susceptibility of the stem and branch tissues coincides with the presence of a copious inoculum from the over-summered leaf-spot stage of the disease, and it is therefore the most likely period for infection.

More direct evidence that the leaf scar is an important avenue of infection has now been obtained by experimental inoculation of leaf scars in the autumn. The laminæ of the leaves on selected fruiting spurs were excised in October, thus inducing abscission in the petioles, which were then readily detached after ten days. Spurs with the leaf scars thus exposed were inoculated immediately, and at varying intervals afterwards. No wounds were made, and the inoculum, an aqueous suspension of a 48-hr. culture of *Ps. mors-prunorum*, was applied to the scars with a loop. The results of one experiment, recorded the following May, are summarized in the accompanying table.

Interval between exposure of scar and inoculation	No. of spurs inoculated	No of spurs killed	No. of killed spurs developing branch cankers
0 days	103	101	40
3 days	102	70	37
8 days	96	32	14
Uninoculated controls	100	0	0

These results are an aggregate for two varieties of cherry, one comparatively resistant and one susceptible to this disease. Approximately the same number of spurs was killed in each; but in the resistant variety only 11 per cent of these led to the formation of branch cankers compared with 63 per cent in the susceptible one. In view of the difficulty frequently encountered of reproducing cankers comparable with natural ones by inoculation through an artificial wound directly into the branch tissues, it is noteworthy that the cankers following inoculations of the leaf scars were indistinguishable in form and severity from those occurring naturally. On the six trees of the susceptible variety, nineteen of the twenty-four branches bearing inoculated spurs died from cankers which had girdled them by the following May.

Preliminary observation and histological studies suggest that the bacteria enter the spur via the vascular traces of the leaf scar.

Fusaria Isolated from South Indian Soils

IN connexion with work on *Fusarium* wilt of cotton in South India, I took up in 1947 a detailed study of *Fusarium* floras of certain South Indian soils, particularly 'wilt-sick' black cotton soils. Wide occurrence of *Fusaria* in soils has been reported from a number of countries, though no such detailed survey has been undertaken in India. The present work was directed towards determining the different species of *Fusarium* that occur in 'wilt-sick' black cotton soils around Udamalpet (Coimbatore District, Madras State), mainly following the techniques of the traditional *Fusarium* investigations of Wollenweber, Reinking and others[1,2,3].

In the isolation of *Fusaria* from soils, the 'root burial' technique[4] was largely used, supplemented by the dilution-plate technique. In general the former gave a much better picture of the *Fusarium* flora than the latter, since *Fusaria* seldom appeared on dilution plates but could be easily recovered from bits of root initially buried in soils and later removed and plated out on suitable media. The following species of *Fusarium* were isolated from Udamalpet soils

1. ***Fusarium avenaceum*** (Fr.) Sacc.
2. ***F. chlamydosporum*** Wr et Rg.
3. ***F. culmorum*** (W.G.Sm.) Sacc.
4. ***F. equiseti*** (Cda.) Sacc.
5. ***F. javanicum*** Koord
6. ***F. javanicum*** Koord. v. ***radicicola*** Wr.
7. ***F. oxysporum*** Schlecht.
8. ***F. poae*** (Peck) Wr
9. ***F. scirpi*** Lamb. et Fautr.
10. ***F. scirpi*** Lamb. et Fautr. v. ***acuminatum*** (Ell. et Ev.) Wr.
11. ***F. solani*** (Mart.pr.p.) App. et Wr.
12. ***F. solani*** (Mart.) v. ***Martii*** (App. et Wr.) Wr.
13. ***F. solani*** (Mart) App. et Wr. v. ***minus*** Wr.
14. ***F. solani*** (Mart.) App. et Wr. v. ***striatum*** (Sherb.) Wr.
15. ***F. vasinfectum*** Atk.

The importance, from the point of view of plant disease, of the occurrence of different species of *Fusarium* in 'wilt-sick' soils will become obvious when it is realized that considerable evidence has accrued in recent years indicating that some wilts and root rots of crop plants are caused by complex infections by more than one species of *Fusarium*. Details of the present work will be published elsewhere.

I am grateful to Prof. T. S. Sadasivan for much guidance and criticism during the course of the present work. My thanks are due to the National Institute of Sciences of India for the award of an I.C.I. Fellowship, during the tenure of which the major part of the work was carried out.

Myxobacteria Mistaken for Nitrifying Bacteria

IN connexion with the communication under this title by Miss Joyce B. Grace, published in *Nature* of July 21, p. 117, a careful re-reading of Winogradsky's papers on the subject[1] leads me to believe that he has described two quite different species under the name of *Nitrosocystis*. In the first place, there is the organism isolated by Romell[2] from forest soil by Winogradsky's later technique of placing grains of soil on the surface of silica gel plates. Imsenecki repeated this work, and obtained *Nitrosomonas*, and a non-nitrifying myxobacterium, *Sorangium symbioticum*[3]. In the second place, there is the zooglœa-forming species, isolated by Winogradsky from Zurich soil by the enrichment culture technique, originally described in 1892 as a *Nitrosomonas*, and reclassified by Winogradsky in 1933 as a *Nitrosocystis*. This species forms the 'hard colonies' mentioned by Kingma Boltjes[4], whose work Miss Grace dismisses with the statement that there was "no evidence that the cultures were pure" ; the cultures in question, however, were single-cell isolations. As regards hard colonies, I have seen them formed by my own pure cultures of an ammonia-oxidizing bacterium, which I have every reason to believe is a *Nitrosomonas*[5]. I think that the formation of hard or soft colonies depends on the density of the silica gel in the plate, and also on whether the colony is buried or superficial ; Kingma Boltjes observed both types on his plates made from pure cultures of *Nitrosomonas*.

I would be inclined to think that the first "*Nitrosocystis*" may be a myxobacterium, but that the second is a true nitrifier, so that the genus *Nitrosocystis* is still valid in this sense, unless further work should show it to be identical with *Nitrosomonas*. I do not feel qualified to express an opinion on the genera *Nitrocystis* and *Nitrosogloea*.

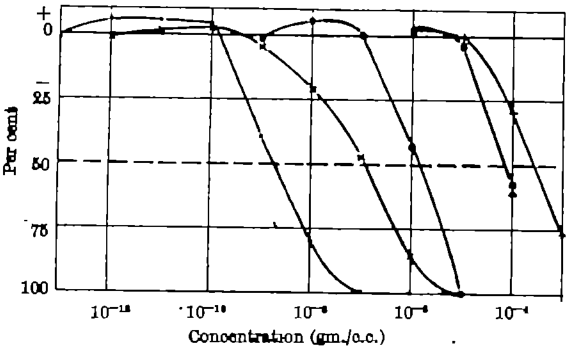
Effect of *cis*-Cinnamic Acid and some Isomeric Compounds on the Germination of Zygotes of *Chlamydomonas*

THE effect of a number of organic acids as inhibitors of germination has been tested on the zygotes of the *blastikos* race of *Chlamydomonas eugametos*[1]. It was observed that *trans*-cinnamic acid inhibits germination to about 50 per cent even at a dilution of 10^{-7} gm./c.c. The experiment has now been extended to the three different allotropic modifications of *cis*-cinnamic acid and a few isomeric compounds. The percentage of inhibition of germination with respect to that of control is shown in the accompanying graph. The experimental method and evaluation have been described in greater detail elsewhere[2]. The percentage germination of the control (in *Volvox* solution) is $85 \cdot 92 \pm 0 \cdot 429$ per cent ($n = 1,186$ zygotes). The activity of cinnamic aldehyde is very small, since at 10^{-4} gm./c.c. the germination remains unaffected. A similar effect is also



Percentage inhibition of germination with respect to control (0-line) cinnamic aldehyde, △—△ . *o*-coumaric acid, □—□; *β-d*-glucosido-*o*-coumaric acid, +—+ ; coumarin, ○—○ ; *trans*-cinnamic acid, ×—× , *cis*-cinnamic acid, ●—●, tested on the zygotes of the *blastitos* of *Chlamydomonas eugametos*. The concentrations for 50 per cent inhibition can be read from the broken line. + is promotion (above the 0-line)

found in the case of *trans*-2-oxy-cinnamic acid (*o*-coumaric acid). β-*d*-Glucosido-*o*-coumaric acid is less active than the aglucone. Coumarin is a hundred times more active; even at a dilution of 10^{-8} gm./c.c. a statistically significant promotion of germination can be definitely observed. Still more active is *trans*-cinnamic acid as has been already reported[1]; though in very dilute solution (10^{-10} to 10^{-12} gm./c.c.) no statistically significant promotion of germination was recorded. The range of activity of *cis*-cinnamic acid is fifty to eighty times more than that of the *trans* form, since even at a dilution of 10^{-11} to 10^{-12} gm./c.c. a significant promotion of germination could be observed. The three allotropic modifications of *cis*-cinnamic acid (42° C., 58° C., 68° C.) have the same activity[2].

The strong activity of coumarin can be ascribed to the opening of the lactone ring and the formation of *cis*-2-oxy-cinnamic acid (coumarinic acid). As the compound is unstable, its effect could not be tested on zygotes of *Chlamydomonas*. It may be assumed that the activity of *trans*-cinnamic acid is due to the formation of *cis*-cinnamic acid during the germination of zygotes, which takes place only in the presence of light[3]. Then it would be expected that, with a sufficiently large number of zygotes, at a dilution of 10^{-10} to 10^{-11} gm./c.c. of *trans*-cinnamic acid, promotion of germination will be observed. The question of the isolation of natural germination inhibitors from zygotes of *Chlamydomonas* remains still open.

New Derivatives of Nitroparaffins and their Antitubercular and Antirickettsial Properties

As I have indicated earlier, the reaction of nitroparaffins with formaldehyde and ammonia or amines may lead to the formation of polymers[1]. Further experiments have shown[2] that a number of new ring compounds of 1 : 3-tetrahydro-oxazine (I and II) and 1-oxa-3-aza-*cyclo*octane (III) type are formed by the interaction of 1-nitropropane with formaldehyde and ammonia. The products can be transformed into hydrochlorides of the open-chain amines (IV), (V), (VI) or methiodide (VII). 2-Nitropropane yields the amine (VIII)[3] with formaldehyde and ammonia.

Recently, my co-workers and I isolated the compounds (IX) and (X) from nitroethane[4] and the compound (XI) from phenylnitromethane[5], formaldehyde and ammonia reaction products. Also, an oxazine (XII) was prepared from 1-nitropropane, formaldehyde and methylamine[6].

All these substances and ω-nitrostyrene (XIII) representing nitroaralkenes and a series of nitro-alcohols deriving from nitroparaffins (XIV), (XV), (XVI) and (XVII) were tested against saprophytic mycobacteria (six strains) *in vitro* in Youman's medium and *in vivo* against *Mycobacterium tuberculosis* ($H_{37}Rv$ strain) in white mice inoculated intravenously. They were also tested *in vivo* against *Rickettsia prowazeki*.

Some of the results of bacteriostatic concentrations *in vitro* are shown in Table 1.

All compounds except (IV) and (XIII) possess a relatively low toxicity. The lethal dose of some of them in rats is given in Table 2[6].

On the basis of these experiments, a few compounds were selected for testing *in vivo* in white mice. The results are shown in Table 3.

Table 1[7]

Substance	I	IV	V	VI	VIII	IX	XII	XIII	XIV	XV	XVII
Bacteriostatic concentrations (mgm. per 100 ml.)	7 5–125	7·5–60	7 5–60	30–60	15–125	15–30	7·5–30	5–15	30–125	30–60	30–60

(The wide range of concentrations was produced by examining the action on different strains.) Substances (VII) and (XVI) were found to be inactive.

Table 2

Substance	Lethal dose (gm. per kgm. of body-weight of rats) Intravenous	Subcutaneous	*per os*

XVII	0·3	—	

After 35 days, all survivors were killed and the extent of tuberculous involvement was noted and rated. Experiments with the substances (I), (V), (VI), (X) and (XIV) are being continued.

Substances (XII) and (XV) were also examined as to their action *in vivo* against *Rickettsia prowazeki*. They proved to be more efficient than *p*-aminobenzoic acid[9]. Inoculated white mice treated with (XII) or (XV) lived for nine days; those treated with *p*-aminobenzoic acid survived four to six days; controls died after three to four days.

Table 3[7]

Identification of a Heparin as a Main Component of the 'Third Factor' involved in the Virulence-enhancing Action of Hog Gastric Mucin

PREVIOUS work[1–4] has shown that the virulence-enhancing action of hog gastric mucin is due to a synergic action between two non-specific factors (a viscous medium and particulate residue), and a more specific soluble third factor. Partial purification of the latter[3] yielded a heterogeneous product which was predominantly peptide in nature, but which contained 5–10 per cent of carbohydrate residues. Further purification, using a revised assay[4] in which the two non-specific factors are maintained constant, has shown that the carbohydrate moiety is responsible for the activity.

After much preliminary fractionation of the crude mucin from fresh hog gastric mucosæ, this moiety was separated into two active fractions by using the different solubilities of their barium salts in water and in aqueous alcohol. Fraction *A* is precipitated from aqueous solution by adding 3 per cent barium acetate at *p*H 7 and standing at 0° for several days. It has been obtained as an amorphous sodium salt, and examination at *p*H 4·5 and *p*H 8·0 by ultracentrifugation and electrophoresis indicates a single homogeneous substance. A typical batch has an activity of 3·9 (2·9–5·1) virulence-enhancing units[4]. Fraction *B* is soluble in aqueous solution containing 3 per cent barium acetate and is precipitated by adding alcohol to 50 per cent v/v. It contains no ester sulphate or hexuronic acid detectable by the Dische carbazole reaction[5], and is still impure, but it is predominantly carbohydrate, containing a high proportion of hexosamine. A typical batch has an activity of 1·1 (0·7–1·8) virulence-enhancing units[4]. Purification of this compound is being continued.

Active heparins are mucoitin sulphuric esters in which the number of sulphate groups can vary considerably[6]. Chemical analysis of the essentially homogeneous fraction *A* clearly indicates that it is a heparin. This has been further confirmed by comparing the anticoagulation activity of fraction *A* with that of three different, highly active, samples of authentic heparin which were also assayed for virulence-enhancing activity. In addition, my colleague Dr. H. P. Lambert had found that fraction *A* inhibits

sheep-cell hæmolysis, and that this effect is due to an anti-complementary action. Heparin has already been shown to be anti-complementary[7].

Table 1 shows the more important analytical figures for fraction *A*, the slightly acid reaction (*p*H 5·5–6·0) of which indicates that the final dialysis, to remove sodium sulphate after decomposition of the barium salt at *p*H 7, has resulted in a loss of sodium ions and produced a mixture of acid and neutral salts. Figures published by Reinert and Winterstein[8], and Wolfrom *et al.*[9] for the neutral sodium salt of heparin, are included in the table, together with those calculated for an average polymer unit composed of a mucoitin disulphuric ester. Other relevant experimental data for fraction *A* which have already been found true for heparin are the absence of acetyl groups detectable by *p*-toluene sulphonic acid hydrolysis[9,10], a Van Slyke amino-nitrogen figure which increases with reaction time[9], the wide discrepancy between the Dische and Tollens–Lefèvre methods of estimating hexuronic acid[9], the presence of *d*-glucosamine[9] as detected by paper chromatography, the presence of a free carboxyl group[9], and the crystallization of an acid barium salt in micro-sheaves[9].

Table 2 shows a comparison of the anticoagulation activity of fraction *A* with that of three different, highly active samples of heparin from Boots Pure Drug Co., Ltd. (102 I.U. per mgm.), Evans, Lescher and Webb (93 I.U. per mgm.) and Roche Products, Ltd. (120 I.U. per mgm.). Fresh ox blood (3·75 ml.) was mixed with solutions (0·3 ml.) of different strengths of the samples under test, and the time for complete coagulation was noted using the technique described by Jorpes[12,13]. These results show that fraction *A* has a slightly greater activity than that of the three authentic heparin samples. Corresponding virulence-enhancing activities, when determined by the assay used for the third factor involved in virulence enhancement, are, in the usual units: fraction *A* 3·9 (2·9–5·1); Boots heparin, 3·2 (2·1–4·8); Evans, Lescher and Webb heparin, 2·2 (1·4–3·3); Roche heparin, 3·5 (2·3–5·1). Adequate controls ruled out any possible toxicity of these samples at the concentrations used for the test.

Full details of this work will be published elsewhere. Acknowledgment is made to the Chief Scientist, Ministry of Supply, for permission to publish this communication.

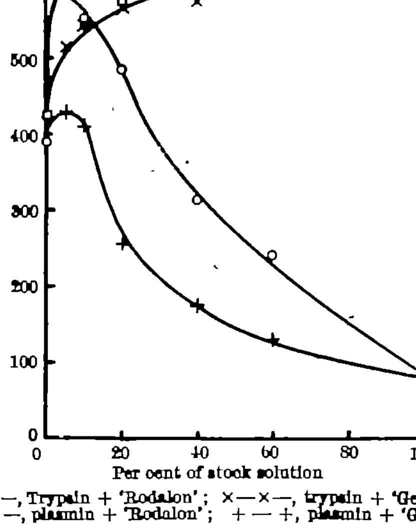
Quaternary Detergents and the Activity of Trypsin and Plasmin

DURING investigations on antiproteolytic substances an interesting action of two quaternary surface-active agents, namely, cetylpyridinium chloride ('Germidin', Bionova, Ltd., Copenhagen) and lauryl-benzyldimethylammonium chloride ('Rodalon', Ferrosan, Ltd., Copenhagen), was observed.

Mixtures of the quaternary compounds with trypsin (Armour, crystalline, containing not more than 50 per cent magnesium sulphate) and plasmin (human, streptokinase-activated) were tested for fibrinolytic activity by means of the plate method[1,2]. The results are presented in the accompanying graph.



□—□—, Trypsin + 'Rodalon'; ×—×—, trypsin + 'Germidin'; ○—○—, plasmin + 'Rodalon'; +—+, plasmin + 'Germidin'

Action of cetylpyridinium chloride ('Germidin', 1 per cent stock solution) and lauryl-benzyldimethylammonium chloride ('Rodalon', 1 per cent stock solution) on the fibrinolytic activity of equal volumes of enzyme solution. *Abscissa*: Concentration of quaternary compound added in per cent of stock solution. *Ordinate*: Fibrinolytic activity recorded as the product of two diameters of the lysed zones

It is seen that the fibrinolytic activity of trypsin is increased considerably by the addition of the quaternary compounds. Plasmin shows an increase in activity in the presence of very small concentrations of the compounds, while larger amounts inhibit. These results stress the difference between trypsin and plasmin as proteolytic enzymes. Chymotrypsin (Armour, crystalline, 50 per cent magnesium sulphate) was slightly inhibited. An *Aspergillus* protease[3] (courtesy of Dr. W. G. Crewther, Melbourne) was activated slightly.

Our experiments have shown that proteolytic enzymes may be characterized and grouped according to the influence of a number of antiproteolytic substances. These investigations will be published in detail elsewhere.

Effect of Temperature on the R_F Values of the Amino-acids during Paper Chromatography with Solvents completely Miscible with Water

CONSDEN *et al.*[1] observed that in the case of phenol saturated with water as the developing solvent, R_F values of amino-acids increase with increase of temperature, since the water-content of phenol varies directly with temperature within the range studied. The reverse is the case with collidine, the water-content of which decreases with increase of temperature. The water-content of solvents which are completely miscible with water can be suitably adjusted, the phase-composition remaining unaffected by temperature. If the change in phase-composition of the developing solvent is the only cause of alterations of R_F values with temperature, they should be independent of temperature in case of miscible solvents. That this is not so will be clear from the following.

The miscible solvents employed were pyridine, acetone and *iso*propyl alcohol. Since these solvents are highly volatile, the ascending method[2] of paper chromatography was followed, using throughout Whatman No. 1 filter paper. The positions of the amino-acids on the chromatogram were, as usual, indicated with ninhydrin. The range of variation in temperature during a particular experiment did not exceed half a degree. The accompanying table records the R_F values at different temperatures of four amino-acids out of a large number I have investigated.

Developing solvent	Amino-acids	R_F values at 10° C.	15° C.	20° C.	25° C.	30° C.
Acetone–water (7 : 3 by vol.)	Aspartic acid	0·23	0·31	0·38	0·63	0·58
	Glycine	0·26	0·34	0·36	0·51	0·51
	Proline	0·46	0·49	0·51	0·65	0·69
	Phenylalanine	0·53	0·63	0·64	0·72	0·72
Pyridine–water (7 : 3 by vol.)	Aspartic acid	0·25	0·27	0·33	0·25	0·32
	Glycine	0·34	0·35	0·38	0·36	0·36
	Proline	0·51	0·56	0·60	0·55	0·52
	Phenylalanine	0·68	0·70	0·71	0·72	0·68
*Iso*propyl alcohol–water (7 : 3 by vol.)	Aspartic acid	0·12	0·13	0·17	0·28	0·17
	Glycine	0·20	0·23	0·27	0·30	0·26
	Proline	0·32	0·40	0·45	0·47	0·44
	Phenylalanine	0·47	0·51	0·56	0·57	0·55
*Iso*propyl alcohol–water (9 : 1 by vol.)	Aspartic acid	0	0	0	0	0
	Glycine	0·02	0·02	0·03	0·04	0·05
	Proline	0·10	0·11	0·11	0·13	0·15
	Phenylalanine	0·17	0·18	0·19	0·20	0·25

These results indicate that in most cases the R_F values increase with rise of temperature, except in the case of pyridine–water at 25° C. and *iso*propyl alcohol–water (7 : 3) at 30° C. At these two temperatures the R_F values show a decrease instead of an increase compared with those at preceding temperatures. A decrease of the partition coefficient at higher temperatures would partly explain an increase of R_F, assuming a constant value for the ratio of areas of cross-section of the mobile and immobile phases.

The decrease in R_F values in the case of pyridine–water at 25° C. and *iso*propyl alcohol–water (7 : 3) at 30° C. is contrary to what one expects from the above reasoning. It is perhaps necessary to take into account a large number of factors involved in paper chromatography which are likely to be influenced by temperature. They include water-adsorption by cellulose, compositions of the phases, affinity of the solvent and solute molecules for cellulose and the solvating power of the liquids employed. A detailed study for evaluating the most likely factors is in progress.

Thanks are due to Dr. J. K. Chowdhury, head of the Department of Chemistry, and Dr. B. Banerjee, senior research fellow, Bose Research Institute, Calcutta, for their encouragement and suggestions during this work. My thanks are also due to Dr. S. K. Mukherjee, University College of Science and Technology, Calcutta, for his criticism and suggestions.

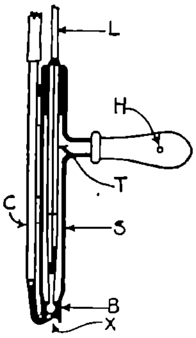
A Convenient 'Hanging-drop' Glass Electrode Unit

A glass electrode unit developed in this laboratory has proved so generally useful that its brief description may be helpful to others. It combines the advantages of providing a robust and convenient assembly for general purposes, and of permitting precise measurement of *p*H with as little as 0·15 ml. of available solution if need be. The form of the unit (which incorporates an effective stirring device) makes it suitable for electrometric titrations on volumes of solution as small as 0·4 ml.



The construction of the electrode assembly is shown in the diagram. The glass membrane is the bulb *B*, about 4·8–5·0 mm. diameter, blown on the end of the drawn-out tube *T* which contains a sealed-in *N* hydrochloric acid/silver chloride half-cell. It is a great advantage that the membrane consists of a type of glass permitting determinations of *p*H in alkaline as well as acid solution.

The electrode is mounted within a glass sleeve *S*, of which the main upper portion is 8 mm. internal diameter, and the short bottom portion about 6·2 mm. A side tube near the top is fitted with a rubber teat; this is perforated by a small hole *H* normally closed by the thumb on compressing. This provides a means of filling, washing, and also of stirring when the electrode is dipped into a small volume of liquid.

The bottom of the sleeve is open. A small notch ground in its bottom edge receives the bent tip of the potassium chloride bridge *C*, which is bound to the sleeve by rubber bands. The tip of *C*, including the bend, consists of a capillary with a sealed-in thread of asbestos fibres which terminates the salt bridge. The tube *C* is connected above to a reservoir (not shown) of potassium chloride into which a small calomel half-cell is dipped, the connexion being made through a length of about 12 cm. of flexible plastic tubing.

The potassium chloride reservoir, and the electrical lead *L*, are clamped on a suitable stand and the electrode assembly is allowed to dangle at a convenient height above bench-level.

The test solution *X* surrounds the glass electrode *B* and is held in place merely by capillarity. It is in contact with the tip of the potassium chloride bridge.

The general method of operation will be clear to any user, but the following may be mentioned: (1) pointed pieces of filter paper may be used to drain the space around the electrode, for example, during washing; (2) to fill when minimal liquid is available, a drop placed at the bend in *C* will enter the space around the electrode.

I wish to acknowledge the helpful co-operation of Messrs. Doran Instrument Co., Ltd., Stroud, Glos, who assisted by developing an appropriate glass electrode for this unit.

A Gravimetric Estimation of the Carboxylic Acid Group in Cellulose

The electrochemical and ion exchange properties of cellulose and other insoluble polysaccharides are largely determined by the content of —COOH groups, so that their precise estimation becomes a matter of some importance. Davidson[1] has recently re-examined the various methods available for their determination, which are based either upon some form of acid–alkali titration, or upon the absorption of the basic dye methylene blue.

We consider most of the defects of these earlier methods are absent in the new method we now describe. The material is soaked in a saturated solution of uranium acetate in water (*c.* 0·01 *M*, *p*H 6·5) over-night, very thoroughly washed, oven-dried and weighed, ashed at 700° C. and the ash weighed as U_3O_8. This procedure applied to commercial 'Cellophane' gave the following results:

mgm. Ash/1 gm. 'Cellophane'	13·56	13·86	13·97
Acid-washed blank	0·1	0·1	0·1

Mean COOH content milliequiv./100 gm. = 4·00.

One of us (G. R. W.) has also estimated the uranium content by weighing in water before and after soaking in uranium acetate, using a hydrostatic balance. An average result of 4·71 milliequiv. COOH/100 gm. was obtained.

The same material gave the following results by other methods:

Neale and Stringfellow's method (ref. 2)	4·76
Methylene blue absorption (ref. 1)	4·806
Pacsu's method (ref. 3)	5·02

William Nicol and Henry Clifton Sorby

In her short article on William Nicol and H. C. Sorby, Mrs. Eyles states[1] that Nicol "seems to have confined himself to making sections of fossil wood, and did not make rock sections". Nicol stated in 1834[2], however, that when he came to prepare sections of fossil plants he "had recourse to a process I had practised upwards of fifteen years ago, in preparing thin slices of the most fragile substances, as calcareous spar, in order to examine their effects on polarized light". The lapidary G. Sanderson had made thin sections after fixing the specimen to a block of wood with lapidary's cement; Nicol's process was essentially to substitute glass for wood and Canada balsam for the cement.

Nicol's collection in the British Museum (Natural History) contains, in addition to petrified plants, a few sections of flint and other pebbles, as well as of coal, cannel and lignite. Alexander Bryson's largely contemporary collection, also in the British Museum, includes sections of various minerals and rocks, and of corals and other fossil animals. There are incidental references to thin slices of minerals in some of Brewster's papers, and the technique had evidently been employed in Edinburgh on a wide range of minerals, rocks and fossils for many years before Sorby came on the scene, even if its applications were not pursued very far, except in the case of petrified plants.

Sorby's 1851 paper dealt with certain sedimentary rocks; but W. C. Williamson, from whom Sorby learnt the technique of preparing thin sections, had already in his classic memoir on "Microscopic Objects in the Mud of the Levant" (1848)[3] examined "thin sections of oolitic limestones from Bristol, Durdham Down, Yorkshire and Skerry". Williamson's interests were primarily biological; but his pioneering efforts are worthy of remembrance in any account of the early history of the microscopic study of rocks.

---

[1] *Nature*, 168, 98 (1951).

[2] *Edin. New Phil. J.*, 16, 157 (1834).

[3] *Mem. Manchester Lit. Phil. Soc.*, (2), 8, 99 (1848).

MY article on Nicol and Sorby was intended to direct attention to two centenaries of especial interest in the history of microscopic petrography, that is, the examination of thin sections of *rocks*, which are, in most cases, mineral aggregates. It is generally recognized that the initial impetus to the development of this most important branch of geology was given by Sorby in the papers to which reference is made in my article; and also that the polarizing prism invented by Nicol and used by Sorby played an essential part in the development of the new science.

Nicol's statement, quoted by Mr. Edwards, certainly shows that he had made thin sections of *minerals*, but so had other and earlier workers. Prof. W. T. Gordon gave a short account of the history of the examination of stony material by means of thin sections to the British Association in 1926[1]. He mentioned there that Brewster made slices of amethyst one-fiftieth of an inch thick as early as 1817. In fact, Brewster made use of thin slices or plates of minerals for his optical studies several years earlier[2].

I am indebted to Mr. Edwards for directing my attention to the paper published by W. C. Williamson in 1848 in which he refers to examining thin sections of oolitic limestone from several localities. Williamson's paper was read in November 1845, and it is worth noting that in August of the same year John Phillips read a paper to a Yorkshire society in which he also refers to the examination of calcareous rocks in transparent sections[3] (a fact unknown to me when I prepared my article). It therefore seems that the advantages of this technique were becoming known in the eighteen-forties, especially in northern England.

That many of the sections made by Nicol and Bryson are preserved in the British Museum (Natural History) has escaped the notice of previous writers on Nicol, and indeed seems to have been unknown even to C. D. Sherborn, in his "Where is the — Collection ?" (Cambridge, 1940). Sherborn noted only that the Nicol and Bryson collections were sold in 1868, and not that they were acquired by the British Museum. An account of these and any similar collections would be useful and interesting, and might provide a clue to the relative priority of Sorby, Williamson, Phillips, and possibly others in this field.

Could an Arms-Race End Without Fighting?

THERE have been only three great arms-races. The first two of them ended in wars in 1914 and 1939: the third is still going on. From so few events we cannot hope to draw any reliable conclusions by statistics. Let us instead see whether an analysis of motives throws any light on the problem. Arms, in peace-time, are intended to overawe possible enemies; therefore the motive of submission must come into the picture. Arms, in peace-time, in fact provoke possible enemies to prepare to defend themselves; so defensiveness must be taken into account. There is also considerable grumbling about the cost of rearmament. The behaviour of large groups of people is more regular and less capricious than the behaviour of individuals. It is instructive to regard large groups as deterministic, and to represent their behaviour by differential equations, provided that we remember that such a treatment is a caricature. The following simultaneous pair of equations were published[1] for that purpose in 1939.

$$dx/dt = ky\,\{1 - \sigma(y - x)\} - \alpha x + g, \qquad (1)$$
$$dy/dt = lx\,\{1 - \rho(x - y)\} - \beta y + h. \qquad (2)$$

Here t is time, x and y are the war-like preparations of the opposing sides, and the other letters are constants. Of these, k and l are positive 'defence coefficients', σ and ρ are positive measures of 'submissiveness', α and β are positive measures of the objection to the cost of rearmament; but g and h, which represent feelings, not about arms but about the treaty-situation, may have either sign. The names of the opposing nations do not appear, because the motives are supposed to be common to mankind; but the numerical values of the constants may differ from nation to nation.

The validity of these equations was reconsidered in more detail, and by comparison with more historical evidence, in a microfilm[2] published in 1947. The equations were found to be a tolerably good representation of what had happened. Better measures of x and y were introduced under the name of 'warfinpersal', which means the annual 'defence' expenditure divided by the annual earnings of a semi-skilled engineer. By the time that an arms-race had grown to alarming proportions, it was found to be difficult to distinguish the effects of α, β, g or h, for they were swamped by the effects of k and l. The ratio of k to l was reasonably regarded as equal to the ratio of the 'sizes' of their two respective groups as measured by population and industrial development.

The coefficients σ and ρ were originally introduced to represent the well-known fact that great Powers have sometimes suppressed very much smaller Powers without any fighting. The present note is about a comparatively subtle question, namely, the effects of submissiveness between two Powers that are in some sense equal. It will now be shown that the above equations (1) and (2) indicate the possibility that an arms-race might end without any fighting. I first noticed this theoretical possibility in April 1951. A preliminary note about it has been sent to Prof. C. C. Lienau of Columbia University for his book on "Measures of Organization".

The present world-tension between the devotees of communism and of private enterprise is between two groups sufficiently nearly equal to be alarmed about each other. For the sake of mathematical simplicity, let us represent this approximate equality by setting $k = l$, $\alpha = \beta$, $\sigma = \rho$; and let us neglect g and h. Equations (1) and (2) then become

$$\mathrm{d}x/\mathrm{d}t = ky - k\sigma y^2 + k\sigma xy - \alpha x, \qquad (3)$$

$$\mathrm{d}y/\mathrm{d}t = kx - k\sigma x^2 + k\sigma xy - \alpha y. \qquad (4)$$

It happens to be easier to discuss $(x + y)$ and $(x - y)$ rather than x and y separately. From (3) and (4) by addition and subtraction it follows that:

$$\mathrm{d}(x + y)/\mathrm{d}t = (k - \alpha)\,(x + y) - k\sigma(x - y)^2, \qquad (5)$$

$$\mathrm{d}(x - y)/\mathrm{d}t = -(k+\alpha)\,(x-y) + k\sigma(x^2-y^2). \qquad (6)$$

The relations are further clarified by dividing (5) and (6) respectively by $(x + y)$ and $(x - y)$; for then

$$\mathrm{d}\log(x + y)/\mathrm{d}t = (k - \alpha) - k\sigma(x - y)^2/(x + y), \qquad (7)$$

$$\mathrm{d}\log|\,x-y\,|/\mathrm{d}t = -(k + \alpha) + k\sigma(x + y). \qquad (8)$$

There was a time, during 1945 or 1946, before the present arms-race began to be mentioned. It may, nevertheless, have existed in embryo unnoticed, on one hand in Russia's tardy demobilization, and on the other in the United States' secrecy about the atomic bomb.

For mathematical simplicity it is convenient to contemplate an origin of time, say t_0, at which x and y were positive but both so near to zero that the last terms in (7) and (8) were negligible, leaving approximately:

$$\mathrm{d}\log(x + y)/\mathrm{d}t = k - \alpha, \qquad (9)$$

$$\mathrm{d}\log|\,x - y\,|/\mathrm{d}t = -(k + \alpha). \qquad (10)$$

The second member of (10) is negative, so that $\log|\,x - y\,|$ was tending towards minus infinity, and therefore x was tending to equal y. This is the equality of power, which many people rashly regard as a security. The second member of (9) is positive, so that $\log(x + y)$ was increasing. This is the arms-race beginning slowly and inconspicuously.

Next let us contemplate various later times at which $(x - y)$ is practically zero, but $(x + y)$ has grown enough to make the arms-race noticeable. In this stage the last term in (7) is more negligible than it was at t_0, because after t_0 its numerator has decreased, while its denominator has increased. So, in accordance with (9), the sum $(x + y)$ continues to increase exponentially. Therefore, a critical time, t_1 say, arrives after which $k\sigma(x + y)$ becomes greater than $k + \alpha$, thus making $\mathrm{d}\log|\,x - y\,|/\mathrm{d}t$ become positive. But because $\mathrm{d}|\,x - y\,|/\mathrm{d}t = |\,x - y\,|\,.\,\mathrm{d}\log|\,x - y\,|/\mathrm{d}t$, and because $(x - y)$ is practically zero at t_1, there may be a long lingering after t_1 before $(x - y)$ deviates notably from zero. In other words, $(x - y)$ has been in equilibrium at zero, and at t_1 this equilibrium becomes unstable, so that a chance disturbance may cause either x to exceed y, or y to exceed x. The national politicians would be chiefly interested in which of these two ways the change began; but to that question the answer given by the equations would be untrustworthy, because of chance. The cosmopolitans and the non-politicals might have more cause to remember the subsequent changes described in the next paragraph.

Equation (7) shows that immediately after t_1 the sum $(x + y)$ goes on increasing. Yet, when $(x - y)$ has deviated sufficiently from zero, there will come a second critical time, t_2 say, after which $k\sigma(x - y)^2/(x + y)$ will become greater than $(k - \alpha)$, thus making $\mathrm{d}\log(x + y)/\mathrm{d}t$ negative. But because $\mathrm{d}(x + y)/\mathrm{d}t = (x + y).\mathrm{d}\log(x + y)/\mathrm{d}t$, and because $(x + y)$ is large and positive, the change in $(x + y)$ after t_2 will come on without delay. The contrast between these two reversals may be expressed by saying that $(x - y)$ was in equilibrium at t_1, but $(x + y)$ was far from equilibrium at t_2. The decrease of $(x + y)$ would be obvious as the end of the arms-race.

Both these theoretical reversals are consequences of submissiveness, for they would not occur if σ were zero in (7) and (8).

So say the equations (3) and (4). But could events really happen thus? As far as I know, they never yet have done so. Nevertheless, as the more general theory (1) and (2) has been verified in several other cases, it seems desirable that the topical case (3) and (4) should be published for discussion before the actual event becomes known.

The foregoing description is likely to be received with general incredulity, because it asserts, after the manner of Bertrand Russell's 1914 pamphlet called "War the Offspring of Fear", that the motives in the present arms-race are mutual; whereas the reader, whether he believes the capitalist or the communist propaganda, has been told that the arms-race is all due to the aggressiveness of the other side. I can scarcely hope to dispel a prejudice that is so natural anyway, and is daily reinforced by broadcasts and newspapers. Some evidence about present mutuality has been brought back from the U.S.S.R. by Prof. Kathleen Lonsdale.

There may be among the learned another quite minor cause of incredulity, namely, that the above simple argument is mainly about maxima and minima, and does not give a fully quantitative solution of the differential equations (3) and (4). These do not belong to any of the simple types treated in the text-books. Indeed, it seems remarkable that one can obtain considerable insight by a discussion of maxima and minima. The equations have, however, been integrated numerically in a particular case, and some approximate formulæ have been found. The constants have been roughly determined thus: $\alpha = 2$ year^{-1}, $k = 4$ year^{-1}, and perhaps $\sigma > 0{\cdot}4$ per million people. But an account of these doings might easily double the length of this article.

FORTHCOMING EVENTS

Monday, October 1

Society of Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. S. F. Smith: "The Application of Electronic Instruments to Industry".

Tuesday, October 2

Institution of Post Office Electrical Engineers (at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2), at 5 p.m.—Dr. J. Swaffield and Mr. D. L. Richards. "Transmission Performance of the Telephone Network—a Survey of some Basic Problems".

Wednesday, October 3

Institute of Petroleum (at Manson House, 26 Portland Place, London, W.1), at 5.30 p.m.—Prof. F. H. Garner: "The Training of a Technologist" (Redwood Lecture).

Society of Public Analysts and Other Analytical Chemists (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Scientific Papers.

Thursday, October 4

Textile Institute, Lancashire Section (at 16 St. Mary's Parsonage, Manchester), at 6.30 p.m.—Mr. G. K. Lake: "Developments of the New Synthetic Fibres in the U.S.A.".

Friday, October 5

Royal Statistical Society, Industrial Applications Section, London Group (at the E.L.M.A. Lighting Service Bureau, 2 Savoy Hill, London, W.C.2), at 6 p.m.—Mr. L. S. Vallance: "An Experiment on the Accuracy of Time Studies".

British Institution of Radio Engineers, Scottish Section (at the Institution of Engineers and Shipbuilders, Elmbank Crescent, Glasgow), at 7 p.m.—Dr. E. G. Richardson. "Acoustics in Relation to Radio Engineering."

Friday, October 5—Saturday, October 6

Physical Society (in the Physics Department of the Royal Cancer Hospital, Fulham Road, London, S.W.3).—Meeting to be held on the occasion of the Centenary of the Royal Cancer Hospital, 1851–1951: "Applications of Physics in the Diagnosis and Treatment of Cancer".

Friday, October 5.—At 2.30 p.m.

Saturday, October 6.—At 10 a.m.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer (Grade III) and a **Lecturer** (Grade II) **in the Department of Botany**—The Secretary, The University, Edmund Street, Birmingham 3 (October 6).

Chemists, Metallurgists and Physicists (Scientific Officer grade) at a Ministry of Supply research establishment near London, and (for one of the posts under Ref. F.582/51/A) the Royal Aircraft Establishment, South Farnborough, Hants: (Ref. F.582/51/A) **Physical Metallurgists** (3) with research experience in metallography, electron microscopy or X-ray or electron diffraction techniques, for the determination of thermal and physical properties of metals and alloys; (Ref. F.583/51/A) **Physical Chemist or Physicist**, with an interest in metallurgy or ceramics, for research investigations connected with the preparation of novel ceramic materials; (Ref. F.584/51/A) **Physical Chemist or Physicist**, with experience of electron diffraction techniques or of electrochemistry, for work on surface phenomena and for research investigations into the properties of metallic films and coatings—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (October 6).

Research Assistant (graduate in chemistry, with biological interests) for work in connexion with an investigation into silicosis—The Registrar, The University, Reading (October 6).

Secretary to the College—The Secretary, King's College, Strand, London, W.C.2 (October 8).

Lecturer in Physics (preference will be given to candidates interested in mathematical physics)—The Clerk to the Governors, Chelsea Polytechnic, Manresa Road, London S.W.3 (October 12).

Research Appointment (physics graduate) in Microwave Spectroscopy—The Secretary and Registrar, University College, Southampton (October 15).

Research Fellow (with at least two years postgraduate experience in Theoretical Physics, Applied Mathematics, or Metal Physics) to **work in the Department of Metallurgy** on theoretical problems concerning the structure and properties of metals—The Secretary, The University, Edmund Street, Birmingham 3 (October 15).

Lecturer in Production Engineering subjects, including workshop technology up to Higher National Certificate standard, at Denbighshire Technical College, Wrexham—The Director of Education, Education Offices, Ruthin (October 20).

Senior Research Officer (with a university degree with honours in chemical or mechanical engineering, or equivalent qualifications, and with experience in the construction and operation of industrial plant) to undertake the planning and supervision of the design, construction and operation of pilot scale complete gasification plants, in the Division of Industrial Chemistry, Commonwealth Scientific and Industrial Research Organization, Fishermen's Bend, Melbourne—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting No. 3508 (October 20).

Veterinary Research Officers (who must be members of the Royal College of Veterinary Surgeons, or hold a degree in Veterinary Science of an approved university involving a five-year course) in the Research Branch of the Department of Veterinary Service, Southern Rhodesia—The Secretary, Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (October 31).

Lecturer (with university degree or diploma either in engineering or agriculture) **in Agricultural Engineering** at Canterbury Agricultural College, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 12).

Chair of Applied Physics at New South Wales University of Technology—The Agent-General for New South Wales, 56 Strand, London, W.C.2 (November 30).

Assistant (Grade B) **in the Department of Metallurgy and Chemistry** at Rotherham Technical College—The Director of Education, Education Offices, Domine Lane, Rotherham.

Botanist or Plant Pathologist for the Research Division of the Ministry of Agriculture in the Sudan—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, endorsed 'Botanist/Plant Pathologist 4/403'.

Chemists (Principal Scientific Officer grade) at a Ministry of Supply research and development establishment in Buckinghamshire, to work on problems of combustion in solid and liquid propellant rocket motors—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.650/51/A.

Demonstrator in Chemistry—The Registrar, The University, Nottingham.

Head of the Building Department (Grade I) at Burton-on-Trent Technical College—The Director of Education, Education Offices, Guild Street, Burton-on-Trent.

Instrument Engineer (with an honours degree in engineering, corporate membership of one of the Institutions of Mechanical or Electrical Engineers, or equivalent qualifications, and with at least three years practical experience of instrument manufacture) to undertake the design, provision and maintenance of instruments used for the measurement of radioactivity and for the control and recording of pressures, temperatures and the flow of liquids and gases, using electronic and other methods, at the Division of Atomic Energy (Production), Risley—The Ministry of Supply, D.At.En.(P.), Risley, Warrington, Lancs.

Lecturer in the Department of Engineering at the County Technical College, Wednesbury—The Director of Education and Clerk to the Governors, Dept. F.E., County Education Offices, Stafford.

Mathematician (Senior Experimental Officer or Experimental Officer grade) to take charge of, organize and build up a small computing section, and a **Mathematician** (Experimental Officer or Assistant Experimental Officer grade) with interest in applied mathematics or numerical analysis, for a Ministry of Supply research and development establishment south-east of London—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.251/51/A.

Prehistorian (with a good honours degree in archæology) for the Department of Geological Survey, Uganda—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting No. 27079/57/51.

Research Officer (**Biochemist**, with science degree of United Kingdom University and at least two years postgraduate biochemistry experience) for service in Kenya, Tanganyika and Uganda—The Under-Secretary of State, Research Department, Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1.

Senior Lecturer qualified to teach some of the following subjects: Theory and Design of Structures, Surveying and Levelling, Building Science, Strength of Materials up to Higher National Certificate standard in building and civil engineering, and a **Lecturer in the Mechanical Engineering Department** to teach Production Engineering up to at least Higher National Certificate standard—The Secretary, South-East London Technical College, Lewisham Way, London, S.E.4.

Senior Research Officer (with membership of the Royal College of Veterinary Surgeons or equivalent, and a university degree, preferably in Veterinary Science, and at least six years experience in veterinary research work), and a **Research Officer** (with membership of the Royal College of Veterinary Surgeons or equivalent, and a university degree, preferably in Veterinary Science), in the Sudan Veterinary Service—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, marking envelope 'Research Officer 4/220'

LEADERSHIP IN THE MODERN STATE

ON at least three occasions in recent months, Government action in Britain has raised the question of the appropriateness of our existing organization of central government. The establishment of the Ministry of Local Government and Planning, with the re-distribution of functions between the new Ministry and the Ministry of Health, raised fundamental issues that did not receive adequate discussion at the time. Similar issues were involved in the subsequent creation of the Ministry of Materials, while the question of the means of control of the nationalized industries is perpetually being raised, sometimes on Government initiative, sometimes by critics of Government policy. Particular and more limited aspects of the general question have also been discussed from time to time as, for example, in a debate in the House of Lords on the most appropriate means for administering the atomic energy project, and in comments in reports of the Select Committee on Estimates on Treasury control.

Full discussion, free from political bias, of the principles involved is of the first importance. It is the great merit of such lectures as the Romanes Lecture on "The Science and Art of Government" which Lord Hankey delivered at Oxford on June 7, and which has now been published[*], that they enable us to judge the soundness of decisions or proposals in the light of rules or principles of statecraft which are frequently forgotten in the press of business. Lord Hankey postulated, as the main objects of government, peace abroad and contentment at home without too much encroachment on liberty; and in pursuance of the first, which to day is more important than ever, he discussed at some length the reasons for the failure of the Allied Governments to achieve that first object of victory, and the obstacles to their success.

Even here, however, when Lord Hankey traces the real weakness of the United Nations to the fact that it is required to combine the roles of arbiter and belligerent, and thus to become judge in its own cause, his observations have a profound significance for much that is happening in our domestic affairs to-day, and indicate the roots of difficulties there also. Permanent peace cannot be compelled by force, and the important work of the United Nations in the economic, social, cultural and spiritual fields requires supporting by some great and sustained spiritual initiative. Nor has fortune favoured the realization of the second object, "contentment at home without too much encroachment on liberty"; and in considering what could be done to increase contentment Lord Hankey turned largely to the political maxims of the Greeks. First of these, he commends that of avoiding extremes, and refers to criticism of post-war governments of Britain for driving political theories like nationalization to extremes and for wasting public money on untested schemes of Colonial development. The latter lesson would appear to have been learned at last but at great cost, and it is further emphasized in a passage in the last report from the Advisory Council on Scientific Policy.

---

[*] The Science and Art of Government. By the Rt Hon. Lord Hankey. (The Romanes Lecture delivered in the Sheldonian Theatre, 7 June 1951.) Pp. 34. (Oxford: Clarendon Press; London: Oxford University Press, 1951.) 3s. 6d. net.

As regards nationalization, less confidence can be felt, particularly in view of statements about the engineering and the chemical industries. Here, as Lord Hankey proceeds to show, the maxim attributed to Pittacus of Mytilene, "Know thy opportunity", is equally pertinent. He raises the question whether advantages could not have been won from the austerities of to-day by concentrating on overdue reforms that will increase our strength without making demands on financial or other resources needed for rearmament. The timing of action is indeed the key to success, and although Lord Hankey does not discuss particular instances of bad timing that have been responsible for our present difficulties, he makes one important suggestion. It is not nationalization alone, carried out with insufficient regard to the administrative and other resources available for implementing a policy, and too much in subservience to a political doctrine, that is responsible for the strain of overwork on ministers, Parliament and public servants and is already endangering the country's constitution, for all its strength. Lord Hankey rightly observes that the burden of government has been enormously increased by the new and sometimes unnecessary functions imposed by the work of the United Nations and its satellite bodies, the Atlantic Treaty Organization and other developments. This in itself has led to proliferation of commissions, boards, councils and committees at least as much as internal policy. When Lord Hankey's comment is endorsed by the dignified warning about overstrain and illness contained in a note "The Price of Administration", commenting in a recent issue of the *Journal of Public Administration* on the tragic and premature death of Sir Arthur Street, and this is accompanied by the loss of senior Civil Servants from Whitehall to industry, the situation is clearly serious. We are in truth desperately short of experienced administrators in the service of the State, and some of the superhuman load of administrative responsibility must be taken off the shoulders that now bear it.

Something might perhaps be done to check the tendency by making the upper ranks of the Civil Service less financially disparate with those of industry. But a drastic and immediate overhaul of the whole task of administration is desirable, and might also offer surprising economies. Besides avoiding the initiation of measures for the implementation of which trained and experienced staff is not available, it is imperative that there should be a rigorous pruning of all the petty controls and responsibilities which cannot be clearly shown to be necessary in the public interest. Not the least is this necessary in those departments such as the Board of Trade, which, already structurally weak and carrying an absurd load of duties, has recently lost its permanent secretary, Sir John Woods, who has gone to the English Electric Co. There is little hope of rapidly increasing the number of trained senior Civil Servants, and practically the only hope of relief is to prune, wherever possible, the activities of Government.

Lord Hankey made a second practical suggestion—that the whole population should be instructed how to obtain adequate nutrition from austerity rations, by correctly balancing proteins, carbohydrates, fats, vitamins and mineral salts and by other measures which would greatly improve national health, avoid dental decay and effect important economies. Science, as he points out, has already given the lead here, and to achieve success the wholehearted co-operation of the medical profession, nurses and scientific workers from many fields would be required. It is a matter involving not the expenditure of great sums on nutrition but a great deal of education, and here the wider connotation of Lord Hankey's suggestion is important.

Nearly fifty years ago, in the last speech of his South African tour, Mr. Joseph Chamberlain observed: "Everything depends, in administration and in high politics, upon the extent to which those who govern and those who are governed are able, to some extent at any rate, to put themselves in each other's places". Failure to do so, to observe what is from one point of view in national affairs the Solon maxim, "Know thyself", has been a main cause of many difficulties in which Great Britain now finds itself. With it, however, has gone disregard of the maxim of Thales—"Suretyship is the forerunner of ruin"; and there is no more searching passage in Lord Hankey's lecture than that in which he shows how neglect of this precept is inherent in the conception of the Welfare State and, if not watched, can bring all to ruin.

Lord Hankey concludes that while there is no ground for complacency, until rearmament has made further progress, there is no reason for pessimism. Nevertheless, we must avoid waste and dissipation of our scientific and other resources. With that latter problem Lord Hankey was concerned more particularly in a subsequent lecture on technical and scientific man-power given on August 29. This lecture was the fourth in a series of Centenary Lectures on "The Worker in Industry", arranged by the Ministry of Labour and National Service (now issued by the Ministry), and in it Lord Hankey referred to the large groups of workers in science and technology, grouped sometimes by professions, sometimes geographically, sometimes in government service, sometimes in private industry or groups of industries, whose higher direction and co-ordination call for a special type of scientific and technological administrator who is not easy to find. There is in science and technology, he said, the same need as in the Services for a cadre of persons qualified for such directorate and co-ordinating responsibilities at the highest level.

It is suggested by Lord Hankey that aspirants to such posts should have some establishment comparable to the Imperial Staff College, where they would gain a more intimate knowledge of sciences and technologies other than their own, and would meet people with totally different experience in various branches of government and administration, finance, economics, humanities and international affairs. This appears to be advocating a scientific and technological staff college on the model of the Imperial Defence College. It was never the intention, however, that scientific men and technologists with administrative gifts and destined for administrative responsibilities should be excluded from the Administrative Staff College already established at Henley. In such a college they would assuredly more readily correct the deficiencies of specialization and broaden their outlook than in a separate scientific staff college, and in doing so would help to diffuse a much-needed understanding of science into government, the humanities and other spheres of national life.

It will not, of course, be easy as yet to find scientific men and technologists with the general knowledge and administrative ability required to organize and lead the mixed teams of large-scale scientific and industrial enterprise. Measures of reform in secondary as well as in scientific and technological education are necessary, as well as a greater readiness in government and in industrial circles to admit to administrative responsibility the scientific worker or technologist who shows evidence of such gifts. It may even be necessary to encourage him to use them; but although the men with whom we are here concerned will always be relatively few, there must be no attempt to increase the number of administrative positions. That must always be kept at the minimum consistent with efficiency: the present proliferation, as Lord Hankey remarked in his Romanes Lecture, is partly a consequence of so overburdening our administrators that they are unable to cope with the perennial task of reviewing organization.

In his later lecture, Lord Hankey touched on a question of government that is to some extent new, though of growing importance. Government, he emphasized, is concerned primarily with human beings, and accordingly human relations and human personality are dominating considerations. That applies equally to the question of technical and scientific man-power: without a large and adequate number of human beings highly trained for research, development and manufacture, science would decline, progress would be arrested and degeneracy result. In his Romanes Lecture, however, Lord Hankey's major concern appeared to be lest in the Welfare State we should sap, especially in the young, the sterling qualities which have made Britain great. Disaster could easily follow a policy of safety first, a decline in the spirit of public service or of adventure. In industry, as well as in maritime life, enterprise, a readiness to accept responsibility and run risks and to make ventures are as essential as in science or any other creative activity. There are elements in our society to day which threaten this spirit and discourage the adventurous, and of these Lord Beveridge gave plain warning in presenting his reports on 'social insurance' and on 'voluntary action'. It should be a first canon of statesmanship to avoid all measures which threaten the growing-points of science, art or industry, and to encourage as far as administrative action can the individuality and the spirit of enterprise which are the roots of national greatness.

Misgivings on this score are the real reason for the concern manifested, for example, in the House of Lords debate on the administration of the atomic energy project. It is vital to the future of Great Britain that conditions of service should be such as to attract the right type of men and women into the scientific and technological departments of the State, and encourage their most fruitful and creative use. Even now, despite the observations of the Barlow Report on scientific staff and the comments of the Select Committee on Estimates in 1947, the position is not entirely satisfactory. The right use of the scientific and technical expert and the proper relation between science and technology demand more attention than might appear from Lord Hankey's lecture; but none the less he indicates the principles which should determine that use and relation. Equally, his principles might be applied to the consideration of the measures affecting the organization of government and its efficiency. Treasury control of expenditure, although necessary to avoid waste, is a relatively minor matter. Suggestions of the Committee on Public Accounts for strengthening that control, including the appointment of Treasury nominees on semi-independent bodies financed from public funds, and for defining and strengthening the link between the departmental accounting officers and the Treasury, while valuable in themselves, become trivial unless the general policy of the central government is encouraging the initiative and enterprise on which Lord Hankey lays such stress.

That much is strongly contended, for example, in a recent memorandum from the Federation of British Industries, and apart altogether from party politics there is reason for doubting whether the whole basis of taxation policy is now in keeping with the country's long-term interests, and the need for encouraging research and development. An impartial examination of this issue is the more desirable since the ability of the private trust or corporation, such as the Nuffield Foundation, to continue to sustain the growing-points of science by voluntary effort is in doubt. Furthermore, the work of government rests to a large extent not only on the Civil Service but also on the services of an immense number of voluntary workers, in borough councils and magistrates' courts, hospital management committees, governing bodies of schools, and the like. Without this voluntary service the task of government, particularly of local government, could not be carried on. Quite apart from the continuance of that spirit of public service to which Lord Hankey referred, it is important that men and women of the right type should be forthcoming for such work in sufficient numbers. There are changes in social and economic conditions which are tending to check the supply, and on that ground alone an early review of local government is desirable. But Lord Hankey's lecture indicates clearly that the first need is some clear thinking on the whole field of central and local government organization, and an honest attempt to apply firmly and courageously the principles the soundness of which has been attested by more than two thousand years of human experience.

FORECASTING THE WEATHER

Neue Methoden der Wetteranalyse und Wetterprognose

Von Dr. Richard Scherhag. Pp. xii+424. (Berlin, Göttingen und Heidelberg: Springer-Verlag, 1948.) 78 D. marks.

WITHIN the past twenty years the forecasting of to-morrow's weather has become a much more formidable task than it was in earlier years. This comes about not so much because more precision is expected, but because the forecaster is now required to analyse so many more reports and to apply so much recently acquired knowledge of the atmosphere before he can make a satisfactory assessment of the probabilities. Even then he can seldom do justice to his forecast, because of limitations of newspaper space and broadcasting time; but that is another matter.

Until the 1930's, the surface weather chart with its sea-level isobars was the forecaster's main tool; with it he achieved a measure of success which in retrospect is surprising. He always knew that there must be close links between the behaviour of the low- and high-pressure patterns on his surface charts and what was going on in the free atmosphere; but he had not enough information to study the mechanism. Then the application of radio and radar to the measurement of the meteorological elements in the atmosphere and improvement in the means of collecting reports from wide areas provided the forecaster with what he needed; but the new flood of information also brought new problems, not the least of which was the devising of practical and speedy means of analysing and assessing the great mass of surface and upper-air observations which poured on to his bench from the greater part of the hemisphere several times a day.

It is mainly with this problem, and with the summarizing of his long experience in applying upper-air analysis to day-to-day forecasting in Germany, that Dr. R. Scherhag's treatise is concerned, and its importance lies in the fact that it is written from the point of view of the practising forecaster. So many books have been written on meteorological theory and so few by experienced forecasters for forecasters. Dr. Scherhag has divided his book into five major parts dealing respectively with (1) the bases of synoptic meteorology, (2) the climatology of the upper atmosphere and its relation with weather, (3) three-dimensional analyses of weather situations, (4) forecasting procedure in Germany, and (5) long-period forecasting. The second, third and fourth parts are particularly valuable, not for any novel ideas they contain—the techniques described have already been adopted or developed and extended independently in other weather services—but for the emphasis on daily forecasting practice.

In Germany the procedure is to prepare contour charts for isobaric surfaces at five levels up to 41 millibars (70,000 ft.) for the standard times of observation each day. After assessing the changes in thickness of the layers between these surfaces which are likely to be brought about by horizontal and vertical movement and by radiation, the future deformations and positions of the upper isobaric surfaces are estimated, taking into account the probable disposition of the pressure patterns on the surface chart in order to keep the whole system mutually consistent. This is the framework which has then to be filled in with considerations of the changing characteristics, history, and movement of the air masses taking part, and of the regions of interaction between these masses, so leading finally to a forecast of the weather over a particular region at a particular time.

Most modern weather services now follow a similar procedure; but as the physics of no single stage is completely understood, either in Germany or elsewhere, varying degrees of empirical treatment necessarily enter, with emphasis on factors which differ from one country to another. To Dr. Scherhag the day-to-day changes in the stratosphere have important interrelations with weather: in some circumstances he may even select the regime at the 41-millibar level as giving the best guide to the future movements of the pressure field lower down. Without denying that the stratosphere may play an important part, forecasters in other services look to lower levels for the dominating factors, and instead of extending their analysis ever higher, as Germany's recent isolation seems to have driven Dr. Scherhag and his colleagues to do, they pay more attention to the hemispherical circulation pattern in the lower half of the atmosphere.

Almost all Dr. Scherhag's 400-page treatise is concerned with forecasting for periods up to 40 hours ahead, and the brief section of 15 pages on long-range forecasting is not encouraging. The author sees little prospect of extending modern synoptic procedures beyond three days, and though other methods, such as the study of weather singularities and periodicities and pressure waves, and the effects of sunspots and volcanic dust, may have their applications, Dr. Scherhag cannot yet foresee any technique for making useful forecasts for longer periods as a regular procedure.

The book is excellently illustrated with more than two hundred diagrams, and has a bibliography of nine hundred items. Dr. Scherhag and his publishers are to be congratulated on making a contribution of first class importance to the literature of weather forecasting.

J. M. STAGG

UNITY AMID COMPLEXITY

Aspects of Form

A Symposium on Form in Nature and Art. Edited by Lancelot Law Whyte. Pp. ix+249 (32 plates). (London: Percy Lund, Humphries and Co., Ltd., 1951.) 21s. net.

THIS is one of the most intriguing books of recent times. It is also one of the most symptomatic. A stage has clearly been reached when thinkers of several kinds, namely, physicists, biologists, psychologists and art-historians, have cast professional discretion aside, and asked what form is, and what—if anything—we know about it. The result is a symposium at once original and, in the best sense, speculative. The discussion hinges upon "the unity of spatial form in relation to complex processes". This cardinal concept is allowed to develop in an almost classical environment, while the details emerge in the modern synthetic manner. (It is as if, writing *S* for spatial form and *C* for complex process, one was invited to put *SRC* and to let the whole subject take shape within the calculus of relations.)

In particular, a crystallographer leads off by showing how visual configuration passes through 'occupation' and finishes with abstract organization. This, of course, is but one way of saying that material objects tend to obey the law of *pragnanz*, as in *Gestalt* theory. It is also a species of homopolar bond with Dr. Arnheim's paper later on, concerning artistic form. Meanwhile, an astronomer contributes a chapter full of interesting twentieth-century views upon that typically Greek theme, permanence *versus* change. Next come a couple of distinguished biological essays, and then one by Dr. H. B. Cott (of camouflage fame) dealing with the appearance of animals, this implying the existence of vision. The subtle point here is the over-riding influence of contrast, itself a variety of form. Later chapters describe brain patterns, and the functional substitute. The editor (Mr. L. L. Whyte) himself concludes with a chronology of form, and a bibliography.

Slight in bulk, this volume yet represents a prodigious effort, the magnitude of which the reader may not realize until he reaches the last few pages. Then he may discern something of the cost, in the hard labour of thought, which the composition and illustrations must have involved. Seldom can the yield have been more worth while. This said, it may not be too graceless to remark upon a few obvious omissions from the book-list; for example, Speiser's profound "Mathematische Denkweise", Beilby's "Aggregation and Flow of Solids", and E. S. Russell's "Directiveness of Organic Activities", all immediately concerned with the growth of pattern. Incidentally, Koehler's book (p. 246) deals with a multitude of facts, and its title needs an 's' accordingly. Naturally, it is fully recognized that the present volume has been produced in connexion with an exhibition of contemporary art, and that therefore its bias (in so far that it has one) is in that direction.

Nevertheless, there is at least an equal need for a corresponding treatment linked specifically with classical art, including humanist architecture. Some material already exists for such a venture, and even the people to undertake it. But by then, "Aspects of Form" will itself have become a classic.

F. I. G. Rawlins

SOUTH AMERICAN INDIANS

Handbook of South American Indians

Edited by Julian H. Steward. Vol. 6: Physical Anthropology, Linguistics and Cultural Geography of South American Indians. (Smithsonian Institution: Bureau of American Ethnology, Bulletin 143.) Pp. xiii+715+47 plates. (Washington, D.C.: Government Printing Office, 1950.) 5 dollars.

With volume 6, the "Handbook of South American Indians" is complete except for the index. As forecast in the review of vol. 5, the subjects treated are early man (Part 1), physical anthropology (Part 2), and languages (Part 3); but in addition there is a long section on geography and plant and animal resources (Part 4).

The main contribution to Part 1 is a devastating summary by T. D. McCown of previous work, in which he shows that there has been much writing and little progress in the past thirty-five years. Apart from the Argentine remains, none of which has been proved to be of great age, there are various discoveries in Brazil, Ecuador and Lower California which have been held to constitute a Lagoa Santa race. He shows that there are far too few skeletons to support the claim that they form a race, and throws considerable doubt on the antiquity of the Ecuadorian examples. He gives Bird's discoveries of cultural material in South Chile a kindly mention, but does not refer to the single skull, apparently comparable with those of Lagoa Santa, which he was able to reconstruct from a cremation.

The uneven distribution of the available information is particularly apparent in the part dealing with physical anthropology. There are four sections—on skeletal remains, the living Indian, the Mestizos and the physical anthropology of Chile. The last three do not confine themselves to anthropometry, pigmentation and hair, but include also brief general discussions of blood groups and basal metabolic rates, and an account of the physical anthropology of the internal organs of the non-Indian inhabitants of Chile.

The vast subject of linguistics is ably summarized by J. Alden Mason, who emphasizes the incompleteness of our knowledge and disclaims any sort of finality. The plan of this section is a general introduction, followed by notes on each group, with a bibliography. The languages are grouped in larger divisions where possible, but a great many still have to be regarded as independent. A most useful map, in a pocket at the end of the book, accompanies this section.

The final section is much more than mere background. It contains a great deal of information of ethnological and archæological importance, including discussions of the domestication of animals and the origins of cultivated plants; for example, very valuable summaries of recent work on maize and cotton. A recent paper on the Cucurbitaceæ found in the Pre-ceramic deposits of North Peru by T. W. Whitaker and J. B. Bird is not mentioned, but this is an indication, not of omission, but of the inevitable delay in the publication of this volume. Map 7, a relief map of South America, which appears in this section, is so much reduced as to be of little use.

It is impossible to finish this brief notice without expressing once more the immense debt owed by all students of South America to those responsible for the compilation and publication of this "Handbook".

G. H. S. Bushnell

AMERICAN FORAGE AND PASTURE CROPS

Forage and Pasture Crops

A Handbook of Information about the Grasses and Legumes grown for Forage in the United States. By W. A. Wheeler. (Prepared under the auspices of the Field Seed Institute of North America.) Pp. xi+752. (New York: D. Van Nostrand Co., Inc.; London: Macmillan and Co., Ltd., 1950.) 60*s*. net.

As the United States turns to the grass, legume or other forage crop to restore lands, so Britain begins to approach the temporary ley scientifically as a fertility-building crop. Soil conservation may have more spectacular connotations than has the homely phrase, 'good husbandry', yet the aim of the agronomist in either country is to use pasture and forage as improving crops, whatever the starting point. In one sense the practice of leaving land in grass for long periods may be conservation of soil; but we must realize that fertility is fruitfulness rather than some latent quality. One conceives a level of fertility as the rate of all those soil cycles of growth and decomposition which stimulate soil production. In any country, pasture-breaking or forage-cropping accelerates these processes.

Agriculturists in the United States are not only conservation-conscious. As Mr. Wheeler indicates in his introduction, there has also recently developed a spirit of inquiry in the attitude towards range grazings, and the indigenous species are being zealously explored.

For the foregoing reasons we should be acquainted with developments in the United States, and it is from this point of view that we judge Mr. Wheeler's encyclopædic work.

The collation of agricultural experience is an arduous task. The scientific evidence is often meagre, and a host of advisory bulletins is largely compounded from general observation and more than a little speculation. Mr. Wheeler has devoted almost one-half of his book to an agronomic treatise based, with due acknowledgment, on this type of publication. Difficult though the task may be, the material needs more facts and much more winnowing before it is acceptable as a work of reference. Even in view of the enormous amount of material used, and the impressive list of references, it would not be unfair to criticize the disjointed and often repetitive reading which this section makes, because much of it is clearly intended for continuous reading.

The serious deficiency, however, is in basic facts. A chapter on inoculation of legumes contains numerous statistics but little scientific information. The sponsors of the work might have invited specialists to contribute directly to this and another section on fertilizers. Mr. Wheeler shows better acquaintance with seed authentication; but his chapter on plant improvement which begins to leaven the treatise with stimulating thoughts eventually disappoints the reader through lack of detail in describing breeding methods.

A chapter on pests, diseases, weeds and poisonous plants makes brief reference to a good range of these visitations. Shades of the advisory leaflet are cast by the frequent appearance of the magic symbols DDT and 2,4-D.

References are listed at the end of each chapter. This may be the only practical way in which they could be cited, owing to the indirect nature of much quotation. A complete bibliography is appended under author and geographical indexes. The subject index is thorough in itself, but relates to pages, and the reader must work his way through chapter references in order to identify authors with their work.

The description of species which forms the major part of the book is historical and agricultural, as distinct from botanical. There is much repetition of the information contained in the general part of the book. To the non-American student of forage and pasture plants, however, this descriptive portion remains the more informative. This is a relative term. A volume clearly offered as a reference book should be a comprehensive yet scrupulously distilled source of information. The present edition cannot be said to attain these standards, and is therefore disappointing. J. O. Green

ASPECTS OF X-RAY CRYSTALLOGRAPHY

Selected Topics in X-Ray Crystallography from the Delft X-Ray Institutes

Edited by J. Bouman. (Monographs on Theoretical and Applied Physics, Vol. 3.) Pp. xv+375. (Amsterdam: North-Holland Publishing Co., 1951.) 76s.

As its title implies, this book consists of a selection of articles by certain acknowledged experts in the field of X-ray crystallography, the common link being their proximity to each other in Delft. It is divided into eight sections ranging from purely general subjects such as structure analysis, distortion in crystals, and investigations in the biological field, to completely specialized ones such as the recrystallization of aluminium, investigations of photographic emulsions, and the degree of crystallinity in natural rubber. Certain types of apparatus, such as the reciprocal-lattice goniometer of de Jong and Bouman, the curved-crystal monochromator, and micro-cameras, are also dealt with in detail. It will be seen, therefore, that the range of interest is very wide, and opportunity is given for the various contributors to deal deeply and intimately with their own subjects. The book is well produced, and, despite occasional lapses in construction and spelling, the English is of a reasonable standard.

Yet the result is unsatisfactory. 'Selected topics' do not form a book, and the present volume has no general theme to give a sense of unity: the selection of contents appears to have been dictated rather by what the various contributors wished to write than by what the editors wished to include, and consequently the range is too wide to be of great value to specialists, and too casual to form a work of reference for the student.

Consider, for example, the first section—on structure analysis. This deals in great detail with the reciprocal lattice and its direct photography; but then there is a jump to the subject of termination errors in Fourier series. The main part of the subject—the determination of the relative phases of the structure factors—is completely omitted.

Moreover, it is difficult to see the justification for the placing of certain chapters. The section on structure analysis continues with chapters on the broadening of Debye–Scherrer lines and on stereographic pole figures. Still more surprising, in this same section there is mention of the Patterson function; but this turns out to be completely different from what is normally understood by that term, and is, in fact, concerned solely with diffraction by small crystals. Such departures from accepted nomenclature can be very misleading, and indicate a lack of contact with workers in other countries.

These faults could perhaps be tolerated if the various articles formed adequate reviews of the particular subjects. By this test, also, the book fails. The articles cover only the particular interests of the authors, and the lists of references are all quite short and far from comprehensive. (For example, although the biological field is included, the name of Bernal does not appear in the index.)

One must therefore regretfully conclude that the effort spent in producing this book has not been worth while. Despite the brilliance of some of the individual contributions, it is not a work that the specialist will feel he must have at his elbow, nor one to which the student can be referred. H. Lipson

The Pharmacopeia of the United States of America (the United States Pharmacopeia)

Fourteenth revision (U.S.P. 14) and the First U.S.P. 14 Supplement. By authority of the United States Pharmacopœial Convention, Inc., meeting at Washington, D.C., May 14 and 15, 1940. Prepared by the Committee of Revision and published by the Board of Trustees. Pp. lv+1068+4. (Easton, Pa.: Mack Publishing Co., 1950.) 9 dollars.

THE fourteenth revision of the United States Pharmacopeia became official on November 1, 1950, only three and a half years after its predecessor. This short period is a sign of the rapid advance of therapeutics and a testimony to the energy of the Committee of Revision. The new work is about 10 per cent longer than its predecessor and contains nearly two hundred new articles.

The drugs thus introduced include acetanilide, aureomycin, chloramphenicol, chloroguanide (proguanil AN), chlorophenothane (DDT), dimercaprol (BAL), diphenhydramine (Benadryl), folic acid, heparin sodium, naphazoline (Privine, but not Priscol), nikethamide, raspberry juice, streptomycin, trimethadone (Tridione), tripelennamine (Pyribenzamine, but not mepyramine), tubocurarine, tyrothricin, and vitamin B_{12}. The list of omissions includes neoarsphenamine, rhubarb, senna, strychnine, tannic acid and thyroxin. Suramin is omitted and then reintroduced in the first supplement, which becomes official on the same day as the Pharmacopeia (for which this simplified spelling is adopted). Most of these changes were inevitable, though it is perhaps surprising that acetanilide and raspberry juice are introduced now, and that nikethamide was not introduced sooner. It seems likely that thyroxine will be reintroduced before long.

The Committee is to be congratulated on this work, which is very up to date and will be much studied not only in the various American republics where it has official status, but also in other countries which are busy preparing new editions of their own pharmacopœias. It is hoped that before long the appearance of the international pharmacopœia will simplify the labours of the various national committees. In the meantime, there is evidence of collaboration between the British and American committees. Most of the new American names are the same as the new British names, although the Americans evidently could not go so far as to adopt the therapeutically suggestive name 'leptazol' to describe the drug which they now introduce as pentylenetetrazol.
J. H. G.

Physical Chemistry

By Prof. Walter J. Moore. (Prentice-Hall Chemistry Series.) Pp. ix+592. (New York: Prentice-Hall, Inc., 1950.) 6.65 dollars.

PROF. W. J. MOORE has written for university students who have acquired a knowledge of physics and of advanced mathematics. Indeed, the book affords a fine opportunity of testing a student's ability to apply his mathematical knowledge. As is to be expected, the author's approach to the subject is by the way of thermodynamics. The contents comprise: physicochemical systems, the laws of thermodynamics, chemical equilibrium, the kinetic theory, the structure of atoms and molecules, nuclear physics, particles and waves, chemical statistics, crystals, liquids, electrochemistry, surface chemistry, and chemical kinetics. Each chapter opens with a brief, scholarly written, historical account of the concept in question. This is followed by the formal treatment, which is precise, critical and thorough. The author does not make a gift of the mathematical expressions of the laws and relationships he discusses, but builds up his equations from first principles. Each chapter ends with abundance of questions, numerical problems and well-selected reading references. This is an excellent book, but suitable only for those whose mathematical equipment goes at least as far as partial differentiation.
G. F.

Transformation Calculus and Electrical Transients

By Prof. Stanford Goldman. Pp. xiv+439. (New York: Prentice-Hall, Inc.; London: Constable and Co., Ltd., 1949.) 30s. net.

IN the theory of electric transients, the technique of the Laplace transform is a convenient central topic from which Prof. S. Goldman surveys impedance operators, complex variables, partial differential equations, and special functions, particularly the Bessel functions. The Laplace technique is developed from the beginning, and the more advanced student of electrical engineering, at or near postgraduate level, should benefit from the careful interweaving of pure mathematics with electrical theory. Attention is given to rigorous demonstration, but where proofs are omitted, for reasons of length or difficulty, references are supplied. The reader is expected to have a sound knowledge of the calculus, and an acquaintance with the concept of complex numbers and with elementary differential equations. The Laplace transform itself is studied as a transformation relating $f(t)$ to $F(s)$ (the author uses s in place of the more usual p) by the equation

$$F(s) = \int_0^\infty e^{-st} f(t)\,dt.$$

This mode of presentation is often more easily grasped by the technical student than the equivalent 'operational' calculus of Heaviside. The electrical theory excludes the non-linear network, but the study of the linear network is fairly comprehensive and up to date, including, for example, a discussion of the stability of feed-back amplifiers.

The Colloid Chemistry of the Silicate Minerals

By Prof. C. Edmund Marshall. (Agronomy, a Series of Monographs prepared under the auspices of the American Society of Agronomy, Vol. 1.) Pp. ix+195. (New York: Academic Press, Inc.; London: H. K. Lewis and Co., Ltd., 1949.) 5.80 dollars.

THIS useful monograph assembles in logical fashion the various aspects of our present knowledge of colloidal systems involving silicate minerals. After a summary of the main types of silicate structures the author discusses the distinctive properties of the zeolites, notably the adsorption of vapours. The major part of the book, however, deals with the clay minerals. Prof. C. E. Marshall has done a real service in thus bringing together the diverse facts on the physics and chemistry of clay systems which have been revealed in recent years by a variety of techniques. Each chapter is documented with a good list of references and a nice balance has been struck. The reader will benefit from the author's wide and critical reading in being guided immediately to the more important papers in the field. There is much in this short book of value not only to workers in the field of soil science but also to mineralogists and to chemists interested in colloidal phenomena generally.

BRITAIN'S SCIENTIFIC SHRINES (7)

By Eng.-Captain EDGAR C. SMITH, O.B.E., R.N.

THE NORTH-EASTERN COUNTIES

AN itinerary through Yorkshire for a student of the history of science would take him from Sheffield in the south to Middlesbrough in the north, and from Whitby in the east, where stands the statue of Captain Cook (1728–79), to Settle in the west, the birthplace of Dr. George Birkbeck (1776–1841), who as the successor of Garnett at the Andersonian Institution, Glasgow, became imbued with the idea of furthering the education of the working classes. "Standing at the end of a long period of history, in which the fountains of learning had been enclosed for the benefit of a dominant caste [he] recaptured the tradition of the great medieval founders by taking knowledge to the people." A pioneer of mechanics' institutions, from 1804 onwards, as a London physician, he was always to be found in the ranks of the reformers. Birkbeck College, London, is but one of his monuments. He died on December 1, 1841, and was buried in Kensal Green Cemetery. Of Cook there are several memorials in Yorkshire. In Stewart Park, Marton, Middlesbrough, is a granite vase marking the site of the cottage in which he was born, and in the village of Great Ayton stands an obelisk built of stones from Cape Everard, close to Point Hicks, Victoria, Australia. The obelisk marks the site of a cottage occupied by his parents, but which in 1934 was taken down, transported to Melbourne and re-erected in Fitzroy Gardens.

Middlesbrough is a comparatively new town, for a century ago it was a mere village. It now has a population of some 144,000 and in it are to be seen the statues and memorials to the builders of its fortunes, Henry Bolckow (1806–78), John Vaughan (1799–1868), Joseph Pease (1799–1872), Sir Lothian Bell (1816–1904) and Sir Arthur Dorman. Sheffield, on the contrary, has been the home of the cutlery industry for centuries, and its Cutlers' Company was incorporated as long ago as 1624. One important event in its history was the introduction of the crucible process of making steel by Benjamin Huntsman (1704–76). A Quaker and watchmaker of Doncaster, Huntsman set out to produce a finer steel for his springs than he could buy. Removing from Doncaster to Handsworth, he there developed the crucible casting process and later on opened a workshop at Attercliffe, where the firm of B. Huntsman, Ltd., still produces high-class steels. In the Attercliffe old churchyard is its founder's tomb bearing the inscription "Benjamin Huntsman, died 21st June 1776 aged 72 years".

Among Sheffield's other famous men were John Roebuck (1718–94), the son of a Sheffield manufacturer; Mark Firth (1819–80), the steel maker who in 1879 founded Firth College, from which sprang the University of Sheffield; and Henry Clifton Sorby (1826–1908), the founder of metallography. The son of a tool-maker, and always a man of means, from the time he learnt how the Edinburgh investigator William Nicol (1768–1851) had devised a method of cutting thin sections of rocks for microscopical examination, Sorby devoted himself to the study of the structure of rocks and metals, writing some 240 memoirs. He was president in 1878–80 of the Geological Society, which on its centenary in 1907 sent an address to "The Father of Microscopical Petrography". Roebuck, unlike Firth and Sorby, saw little of Sheffield after his schooldays, for he was first a Birmingham physician, then a chemical manufacturer at Prestonpans, and in 1760 the founder of the famous Carron Ironworks, Falkirk. After a life of varying fortunes, he died at Bo'ness and was buried in the Carriden Cemetery. A low wall enclosed his grave and at the back was placed a well-designed marble tablet with a long inscription in Greek and Latin. In 1933 his descendants and the Carron Company carried out a complete restoration of both tomb and memorial.

From Sheffield it is only a few miles to the busy towns of Wakefield, Halifax, Bradford and Leeds, all of which demand notice. No scientific survey, however, would be complete without a visit to Sprotborough, near Doncaster, for here was Sprotborough Hall, the home of Sir Godfrey Copley, Bart. (d. 1709), who by his will left £100 to the Royal Society for "improving natural knowledge". He had been member of Parliament for Thirsk, had held public offices and from 1691 was greatly interested in the affairs of the Royal Society. He died in Red Lion Square, Holborn, London, but was buried in Sprotborough Church. His £100 was allowed to lie idle for some time, but awards were made in 1731, 1732 and 1736, and then the money was used to found the Copley Gold Medal, now the oldest and most famous of prizes in the world of science. Many of its recipients have been mentioned in the course of this survey, but it is of interest to recall that in the forty-six years 1749–95 inclusive, during which forty-one awards were made, no fewer than six of the recipients were Yorkshiremen. In 1749 the Medal was given to John Harrison, a native of Wragby, near Wakefield, for his "Curious Instruments invented and made by him for the exact Mensuration of Time"; in 1759 it was given to Smeaton for his "Curious Experiments concerning Water-wheels and Windmill-sails", and in 1773 Priestley received it for his "Many Curious and Useful Experiments on Different Kinds of Air". Three years later, Cook was awarded it for his "Paper containing the Method he had taken for Preserving the Health of the Crew of H.M.S. Resolution"; in 1783 it was given to the nineteen-year-old boy John Goodricke (1764–86) of York, for his "Discovery of the Period of the Variation of Light in the Star Algol"; and in 1795 to Jesse Ramsden (1735–1800), the son of an innkeeper at Salterhebble, near Halifax, for his "Various Inventions and Improvements in Philosophical Instruments". Harrison (whose wonderful chronometers, it will be remembered, were repaired and set going again by the late Lieutenant Commander Rupert Gould), like Copley, died in Red Lion Square, London, but was buried at Hampstead. Priestley's birthplace was Fieldhead, Birstall, near Leeds, and to Leeds he came from Warrington in 1767 at the age of thirty-four to be minister of the old Mill Hill Unitarian Chapel, a position he held for six years. In Leeds he found much congenial society, having among his friends the Rev. John Michell (1724–93), the rector of Thornhill, who had been Woodwardian professor at Cambridge. In his "Memoirs", Priestley wrote: "In writing the 'History of Discoveries Relating to

Vision', I was much assisted by Mr. Michell the discoverer of the method of making artificial magnets. Living at Thornhill not far from Leeds I frequently visited him and was very happy in his Society as I was also in that of Mr. Smeaton who lived still nearer to me." Smeaton's home was Austhorpe Lodge, Whitkirk, and he died there on October 28, 1792, and was buried in Whitkirk Church. His monument, surmounted by a representation of the Eddystone Lighthouse, was recently reconditioned by the joint efforts of the Smeatonian Society of Engineers and the Newcomen Society. There is no statue of Smeaton, but several of Priestley, one being in the centre of Leeds and another at Birstall. The town of Halifax also has other scientific associations, for here Herschel taught, played and conducted before going to Bath; while in the neighbourhood are Bradley, the birthplace of Sir Henry Savile (1549–1621), provost of Eton and warden of Merton College, Oxford, and Warleywood, the birthplace of Henry Briggs, whom Savile chose as the first Savilian professor of geometry. Two other scientific worthies who came from the same district were Dr. John Radcliffe (1650–1714), a native of Wakefield, whose name is perpetuated in Oxford by the Radcliffe Library, the Radcliffe Infirmary and the Radcliffe Observatory, the last of which has been removed from Oxford to South Africa, and Flamsteed's friend and collaborator, Abraham Sharp (1651–1742), who spent his earlier and later years at Little Horton, near Bradford, and who is buried in Bradford Church. Leeds, too, can claim other distinguished men of science, for Dr. Isaac Milner (1751–1820), who for many years was Lucasian professor and president of Queens' College, Cambridge, was the son of a weaver of the City, and the redoubtable and wealthy Richard Sheepshanks (1794–1855) was the son of a Leeds cloth manufacturer Parson, lawyer, mathematician, astronomer, a renovator of our weights and measures, known to Herschel, Babbage, Whewell, Airy, Baily and a crowd of others, Sheepshanks, whose bust is in Trinity College, Cambridge, was a rare fighter, and of something he wrote De Morgan said that it will "remain to illustrate the science of our century and will furnish ample material to the future collectors of our literary curiosities". From the time Sheepshanks left college, his sister lived with him, and as his heiress she presented £10,000 to Cambridge for research, and gave his instruments to the Royal Astronomical Society.

Before leaving the West Riding of Yorkshire, two other places are worthy of mention: Thurlestone, near Penistone, was the birthplace of Nicolas Saunderson (1682–1739) who, though like Gough of Westmorland blinded in infancy through smallpox, yet became the successor of Whiston as Lucasian professor at Cambridge; while at Sharow, near Ripon, lies Piazzi Smyth, buried beneath a pyramidal stone recalling his much-read book "Our Inheritance in the Great Pyramid". He had retired from the post of Astronomer Royal for Scotland in 1888, and it was at his Yorkshire home near Ripon he carried on his spectroscopic investigations.

To the north of Ripon, and in the North Riding, lie Richmond and Northallerton, the former being the birthplace of Sir Edward Banks, the builder of London Bridge, and of Henry Greathead (1757–1816), the pioneer of the lifeboat, and the latter recalling the work of Colonel William Lambton (1756–1823), who was born at Crosby Grange nearby. Though of humble parentage, by 1781 Lambton had become an ensign. After some active service in India, he was employed on surveying, and from his geodetical work sprang the Great Trigonometrical Survey of India, Sir George Everest (1790–1866) being his chief assistant. Travelling eastward from Northallerton across the Pickering Moors, near Pickering itself is found the village of Cropton, the birthplace of the whaler-captain and magnetician, William Scoresby (1789–1857), who lectured "to the assembly of beauty, fashion and philosophy" at York in 1831. Not long after this, he took holy orders and during 1839–47 was vicar of Wakefield. He died at Torquay. Still farther east and eight miles inland from Scarborough is Brompton Hall, the ancestral home of the Cayley family. The papers of Sir George Cayley (1773–1857), the sixth baronet, have recently been recovered, and they show him to have been a real pioneer in aeronautics. An exhibition of Cayley relics is now being held at Scarborough.

The historic city of York, standing at the junction of the three Ridings, with its splendid Minster, its Archbishop's Palace and its well-known Yorkshire Philosophical Society, brings to mind the two seventeenth-century mathematicians and astronomers, William Neile (1637–70) and William Gascoygne (1612 ?–44), both of whom died in their thirties. Neile was an archbishop's grandson and was born at Bishopthorpe. At Oxford and in London he became known to Wilkins, Seth Ward, Wren and others, was made a member of Council of the Royal Society and at his home in White Waltham, Berkshire, had an observatory. He died there on August 24, 1670, and there he is buried and has his monument. His contemporary, William Gascoygne, was the son of Henry Gascoygne, of Thorpe-on-the-Hill, in the parish of Rothwell, near Leeds. He was as much interested in astronomy as were Horrocks and Crabtree, corresponded with them, and to-day is known to have been the first inventor of the wire micrometer and its application to the telescope. It is considered that he was born not later than 1612, but it is known for certainty that he died at the Battle of Marston Moor, near York, on July 2, 1644, fighting on the side of the Royalists. York is the home of the firm of Cooke, Troughton and Simms, Ltd., which began in the shop opened in 1837 at 50 Stonegate by Thomas Cooke (1807–68). He proved a worthy successor to the instrument makers of the eighteenth century and has been called the 'English Fraunhofer'. He died while engaged on the famous 25-in. equatorial for the Gateshead engineer Robert Stirling Newall (1812–89), who gave it to Cambridge.

Durham and Northumberland, in common with other counties, have given birth to men who in one way and another made their mark in the world of science. Thus the records of the nineteenth century contain the names of such outstanding men as Lord Armstrong and Sir Joseph Wilson Swan. But looking back over the centuries, the year 1701 saw the birth of the somewhat eccentric mathematician William Emerson, a native of Hurworth, near Darlington. For a time he followed his father as a schoolmaster, but took to writing text-books. At the age of sixty-two he walked to London and there he died at the age of eighty-one. His books almost formed a mathematical encyclopædia. Edward Hussey Delaval (1729–1814) belonged to an ancient Northumbrian family. He became a Fellow of Pembroke Hall, Cambridge, in 1759. He was also elected a Fellow of the

Royal Society and in 1766 received the Copley Medal for his "Experiments on the Specific Gravities of the Several Metals". Afterwards he was much concerned in the lightning conductor controversy. Dr. Charles Hutton (1737–1823), the son of a Newcastle colliery worker, started with little education, but rose to be the professor of mathematics at the Royal Military Academy, Woolwich. He was the leading authority on gunnery, and a notable figure in the Royal Society. He retired in 1807 and was succeeded by Olinthus Gregory, but he lived another sixteen years. At his death he was buried at Charlton, Kent. His bust he bequeathed to the Newcastle upon Tyne Literary and Philosophical Society, which had been founded in 1793. Dr. George Peacock (1791–1858), of Thornton Hall, Denton, in Durham, another mathematician, belonged to a later generation. Entering Cambridge at the age of eighteen, he assisted in founding the Analytical Society, which, for the benefit of students, published a translation of the "Differential Calculus" of Lacroix. A man of great charm, in 1836 he became Lowndean professor of astronomy, and three years later also Dean of Ely, where he is buried. At his death, Airy wrote to his widow: "All my debts to other friends in the University added together are not comparable to what I owe to the late Dean . . .". Airy himself had associations with the North, for he was born at Alnwick, where his father was an excise officer.

Whatever interest, however, may be felt in the careers of these and other men of science, for many, the history of Durham and Northumberland is associated with their collieries, railroads, locomotives and ships. Of the leading pioneers of the locomotive, Matthew Murray (1765–1826) of Leeds, William Hedley (1779–1843), John Urpeth Rastrick (1780–1856), George Stephenson (1781–1848), Timothy Hackworth (1786–1850), Robert Stephenson (1803–59), and Sir Daniel Gooch (1816–89) were all born on the banks of the Tyne, and the construction of their historic locomotives "Puffing Billy", "Wylam Willy", "Blucher", "Locomotion" and "Rocket", of the Stockton and Darlington Railway, as also of the Liverpool and Manchester Railway, are landmarks in the history of land transport. There are many monuments to these north-country pioneers, and as recently as 1947 a tablet was placed on Hackworth's house at New Shildon, Durham, while two years later, through the action of the North-East Coast Institution of Engineers and Shipbuilders, the cottage at Wylam in which George Stephenson was born was transferred to the custody of the National Trust.

1951 POPULATION CENSUS OF ENGLAND AND WALES

THE detailed results of the fifteenth Census of Population of England and Wales, taken on April 8, 1951, will be eagerly awaited, as it is twenty years since the last census was taken, 1941 being the first break in the regular series of decennial censuses dating from 1801. It is, however, forty years since there last was a simultaneous count of the population of all the constituent areas of the United Kingdom and the Irish Republic. In 1951 the Census authorities of England and Wales, Scotland, Northern Ireland, the Channel Islands, the Isle of Man and the Irish Republic acted in concert, and a Census was taken on the same day in all these territories. It is to be hoped that this arrangement will continue in future, as the volume of migration between different parts of the British Isles is not inconsiderable and the territorial units which are of interest to students of population are generally larger than the unit covered by one Census authority. It would be of great assistance if definitions and tables in the full reports could be standardized, and summary tables relating to Great Britain, the United Kingdom, and the British Isles as a whole published.

A full appreciation of the results of the Census, which contained a number of new questions asked for the first time on this occasion, will have to await the publication of the detailed reports. The time-lag between Census day and publication will, however, be considerably shortened in England and Wales, for the Registrar General proposes to analyse a sample of 1 per cent of the Census schedules and to publish main tabulations relating to this sample within a year of enumeration.

The preliminary report*, which has recently been published, is, as is customary, based not on an analysis of the actual Census schedules but on a count made from summaries supplied by the local Census officers. Its purpose is restricted, and its main function is to give provisional figures for the total population, classified by sex, of all local-government areas in the country down to district level. For the social scientist its main importance lies in the information it gives on total numbers and on the geographical distribution of the population.

Table 1. TOTAL POPULATIONS AND RATES OF CHANGE IN THE BRITISH ISLES, 1921–51

	Population (thousands)			Rate of change per cent per decennium	
	1921	1931	1951		
England (excl. Monmouth)	35,230	37,359	41,148	+6·0	+4·9
Wales and Monmouth	2,656	2,593	2,597	−2·4	+0·1
England and Wales	37,887	39,952	43,745	+5·5	+4·6
Scotland	4,882	4,843	5,096	−0·8	+2·6
Great Britain	42,769	44,795	48,841	+4·7	+4·4
Northern Ireland	1,258*	1,243*	1,370	−1·2	+5·0
United Kingdom	44,027	46,038	50,210	+4·6	+4·4
Islands in the British Seas	151	143	158	−5·4	+5·3
Irish Republic	3,096*	2,933*	2,959	−5·3	+0·4
Grand total	47,274	49,114	53,327	+3·9	+4·2

* Estimated.

The total populations of the different constituent parts of the British Isles are shown in Table 1, together with their rates of change. To make for easier comparability the rates of change for the twenty years 1931–51 have been converted to average rates for decennia. The table shows that for the British Isles as a whole the population increased at a slightly higher rate between 1931 and 1951 than during the decennium 1921–31. In the United Kingdom, however, the rate of increase remained practically stationary at 4½ per cent for ten years. Within the United Kingdom, Wales, Scotland and Northern Ireland increased in population during 1931–51 after registering a decline in total numbers during 1921–31. This decline, however, was probably due to a negative balance of migration.

Confining our attention to England and Wales, two features of interest must be pointed out. In the first place, for the first time in the past century there has been a net gain of population due to migration. This gain is estimated at about half a million for the period 1931–51. It is due to the return of British subjects resident abroad, the demobilization of Allied and Dominion soldiers in Britain, and to a small part to the immigration of refugees and displaced persons. The net balance of migration from other parts of the United Kingdom can only be estimated since the introduction of the National Register in 1939, and it is believed that this factor accounts for an increase of between 250,000 and 300,000 since that time.

---

* General Register Office. Census 1951, England and Wales. Preliminary Report. Pp. xxxii+52. (London: H.M. Stationery Office, 1951.) 5s.

The second feature that needs comment is that the decennial rate of increase is the lowest ever recorded, in spite of the net gain from migration to which reference has already been made. It is true that since 1931 there have occurred 360,000 deaths, estimated as being due to the War. But the losses of the First World War were much heavier, both absolutely and relatively, than those of the Second, and yet the rate of increase between 1911 and 1921 amounted to 4·9 per cent in spite of a net outward balance of migration. It is therefore difficult to accept the statement in the text that "there is no sign of any tapering away of the successive increments such as would normally be expected to herald the early approach of an ultimate population maximum". The Registrar General's technical advisers must be aware that figures of total population cannot provide any reliable guide to prospects of future development of population, and it would have been wiser to wait for the more detailed information on age distribution and fertility before committing oneself to this view on the future. Taking recent registration figures into account, it would be very surprising if the rate of increase between the present Census and the next will not be substantially lower than 4½ per cent per decennium.

The overall rate of increase for the country as a whole masks considerable variations in the rate of increase for different regions. The geographical distribution of the population has changed since 1931, and the proportionate importance and rates of increase of the different standard regions are shown in Table 2. It is clear from this table that the eastern and southern regions of the country continue to grow at the expense of the north and the north-west. But a new tendency has become evident since 1931. The rate of increase of London and the south-east, which was well above the national average during the previous decennium, has fallen spectacularly and the proportionate importance of that region has decreased. Conversely, the rates of increase of the Midland and south-western region have shot up. It will be interesting to analyse the changes in age, occupational and industrial distribution of the populations of those regions, but this will not be possible until the detailed tables are published.

Table 2. PROPORTIONATE POPULATIONS IN DIFFERENT REGIONS OF ENGLAND AND WALES, WITH DECENNIAL RATES OF CHANGE

Region	Population per cent total			Rate of change per decennium	
	1921	1931	1951	1921/31	1931/51
Eastern	5·8	6·1	7·1	+11·5	+12·8
Southern	5·1	5·3	6·1	+11·3	+11·4
Midland	9·4	9·4	10·1	+ 5·6	+ 8·7
South-western	6·6	6·5	6·9	+ 4·1	+ 7·5
North Midland	7·3	7·4	7·7	+ 6·4	+ 7·2
London and south-east	25·0	25·9	24·9	+ 9·2	+ 2·7
East and West Riding	9·9	9·8	9·4	+ 4·4	+ 2·1
North-western	16·0	15·5	14·7	+ 4·0	+ 2·0
Northern	8·0	7·6	7·2	+ 0·8	+ 1·6
Wales	7·0	6·5	5·9	− 2·4	+ 0·0
England and Wales	100·0	100·0	100·0	+ 5·5	+ 4·6

Some comments have been made on the change in the proportion of the urban population. It appears as though the percentage classified as urban has decreased slightly since 1931. The report shows that this decrease took place almost entirely after 1939. But, again, the figures must be interpreted with caution. There have been no changes in local-government boundaries since 1939, and it is possible that the slight increase in the rural population is merely a reflexion of the increasing tendency of city dwellers to move to the peripheral suburbs, some of which may be classed as rural districts. A detailed study of this question will have to await the publication of the report on place of residence and place of work.

The above remarks make it clear that only very provisional conclusions can be drawn from the preliminary report. New light will be thrown on many problems, however, when the final volumes begin to come out. The abnormally long interval between the past two censuses has been a great obstacle in the way of those who are interested in local or regional studies. It is to be hoped that there will never again be so long an interval between two censuses. Provision was made in the Census Act of 1920 for a census to be taken not more frequently than once every five years, and it is to be hoped that the provisions of the Act will be used and a new census taken in 1956.

E. GREBENIK

SOME EXPERIMENTAL WORK CARRIED OUT IN PHYSICS WITH THE LARGER HARWELL PILE

THIS article describes a few of the experiments which have been carried out in physics at Harwell with the larger atomic-energy pile known as BEPO.

Neutron Crystallography

A double-crystal neutron spectrometer, which utilizes a collimated beam of thermal neutrons from the *thermal column*, has been designed and made for work on neutron crystallography[1], and has been used, among other things, for checking theoretical predictions regarding the intensity of reflexion of monochromatic neutrons from single crystals, with a view to the ultimate use of such crystals in structure analysis. The use of single crystals is clearly desirable if adequate progress is to be made in neutron crystallography, but has been restricted by the appreciable extinction effects arising from the large crystals that have hitherto been employed. From a series of intensity measurements, made under carefully controlled conditions, it has been found that the theoretical intensity relationships worked out by Bacon and Thewlis[2], and Bacon and Lowde[3], according to which the integrated intensity of reflexion is dependent, for thick crystals, not on the structure factor but largely on the degree of mosaic spread, are in fact valid; further study[4], however, has led to the discovery that relatively large crystals can be used if they are of the right shape. For potassium bromide, a crystal typical of many in this field, a specimen 1 cm. long and 2 mm. square in cross-section, permits the proportionality between integrated intensity and structure factor to be retained.

Further, the permitted cross-section may be increased to 4 mm. square by immersing the crystal in liquid air and thus increasing the degree of mosaic spread.

The problem of using single crystals has been attacked on somewhat different lines by Lowde[5], who has constructed a small-scale neutron spectrometer in which crystals of dimensions of only 1 mm. or so are employed. To gain the necessary intensity, the incident radiation is not monochromatized but comes straight from the pile. A convergent beam is used, the crystals under investigation and a special multiple boron-foil ion chamber[6] being set up so that a given crystal plane can reflect into the ion chamber only neutrons of, or near, a particular (chosen) wave-length. The peak counting-rate of the crystal rocking curve then gives the integrated reflexion for the crystal plane in question. The weakness of the method is the inherently possible confusion of orders of a given reflexion, but in favourable cases the method is very encouraging. The peak-to-background ratio obtained with single crystals of naphthalene, for example, is high enough to encourage the hope that information about hydrogenous structures is within our reach, without the need for the substitution of hydrogen by deuterium.

Another way in which the double-crystal neutron spectrometer has been used is for the study of the electron distribution in graphite[7]. X-ray measurements have shown that the $10\bar{1}0$ reflexion relative to the $11\bar{2}0$ is about 85 per cent stronger than expected, and the $10\bar{1}1$ reflexion relative to the $11\bar{2}2$ is about 80 per cent stronger. This could arise if the atomic positions in graphite were other than those generally accepted, or alternatively the electronic configuration might be different from that usually assumed. If the explanation of the anomalous intensities is, in fact, concerned with electronic configuration and not with incorrect atomic positions, then the intensities of reflexion obtained by neutron diffraction should no longer be anomalous, since the neutron scattering is a nuclear phenomenon and no part is played by the electrons. In the event, the measured neutron intensities were found to agree with the theoretical intensities to within 5 per cent, showing that the accepted atomic positions are substantially correct, and that an asymmetric electron distribution probably occurs in graphite.

Irradiation Experiments

The effect of pile irradiation on a number of materials has been studied by X-ray diffraction methods and by electron microscopy. For example, it has been found that the strength of various polymers is seriously affected by such irradiation. Some polymers, for example cellulose and its derivatives and collagen, appear to break down to about the same extent in both the crystalline and non-crystalline parts, whereas others, such as nylon and keratin, first break down in the non-crystalline regions[8].

Some very interesting effects have been obtained by irradiating by slow neutrons in BEPO a copper-gold alloy containing 30 per cent (atomic) of gold, in its ordered state[9]. The first result of the irradiation appears to be an increase of order, as evidenced by a decrease in unit-cell dimensions, and the appearance of satellite reflexions on each side of certain superlattice reflexions, which may possibly arise from the existence of regularly arranged 'domains', although it is too early to be sure of this. The effect is accompanied by a decrease in electrical resistivity. At a later stage the resistivity increases and additional X-ray reflexions occur, the origin of which is not yet understood; but at no stage have the superlattice reflexions shown any loss of intensity. It is possible that further irradiation may produce such a loss, but this question must await further experiment.

In contrast with the above results, it is interesting to note that the irradiation of a similar alloy in a fast neutron flux produces the opposite effect, that is, the alloy becomes disordered[10].

Neutron Spectrometer Experiments

A beam of neutrons from a nuclear reactor will consist of a group of neutrons which have been in approximate thermal equilibrium with the moderator, and a group with energies lying between 2 MeV. and thermal energies. It is often useful to be able to select from this distribution those neutrons the energies of which lie in a narrow band. This may be done either by using the wave property of neutrons to reflect a certain wave-length with a crystal (as in neutron crystallography), or by artificially modulating the beam and then timing the neutrons over a measured path. Spectrometers working on each of these principles are in use with the Harwell pile. The crystal spectrometer is used to obtain a monochromatic neutron beam with an energy anywhere in the range 0·05–10 eV., and a mechanical time-of-flight spectrometer using a cadmium shutter to pulse the beam is used to select neutrons with energy anywhere between 0·001 and 0·10 eV.

These instruments have been used to measure the transmission of samples of several elements as a function of neutron energy. From the measured transmission the probability that a neutron will interact with a nucleus (that is, the cross-section) can be calculated. This cross-section will represent the sum of the probabilities for several different types of scattering and absorption processes. In some cases one process will predominate (for example, absorption in hafnium) and then it is possible to study it alone. In other cases it will be necessary to analyse the 'total' cross-section to find the cross-sections for several processes. The elements molybdenum, bromine, zirconium, hafnium and selenium have been studied in this way, and the results on the first four have been reported[11].

Filtered Neutrons

Neutron beams consisting solely of very low-energy neutrons are useful for certain experiments. It is possible to obtain such a beam by placing a block of polycrystalline material with a low absorption cross-section in the neutron beam, when those neutrons with wave-lengths greater than twice the maximum inter-planar spacing in the crystals will pass through almost unattenuated and neutrons with shorter wave-lengths will be scattered out.

The scattering of neutrons, with wave-lengths too great for Bragg reflexion, by crystalline materials is mainly due to the interaction of the neutrons with the thermal vibrations of the lattice. The scattering in this case will be inelastic, and the gain in energy by the neutron is a measure of the thermal vibration frequency. This phenomenon has been studied in polycrystalline samples of beryllium and iron with a beam of lead-filtered neutrons. The thermal vibration frequency of the C—H bond has also been measured by this method.

Angular Correlation Experiments

Measurements have been made of the angular correlation between the alpha-particles and gamma-rays emitted in the reaction $^{10}B(n,\alpha)^{7}Li(\gamma)^{7}Li$, and between fission fragments and gamma-rays in the slow-neutron fissions of uranium-235. In the boron experiment[12], the distribution was spherically symmetrical to 2 per cent; there was therefore no evidence from this experiment that the spin of lithium-7 is other than $\frac{3}{2}$. In the fission experiment, significant deviations from symmetry up to 20 per cent were observed, and in addition a delayed gamma-ray, of half-life between 10^{-8} and 10^{-7} sec., was observed.

Thin layers of the separated isotopes boron-10 and lithium-6 have been irradiated in a gridded ionization chamber filled with an argon – carbon dioxide mixture, and a 'kicksorter' is used to measure the ionization produced by the disintegration particles relative to that of polonium alpha-particles. The energy-loss to produce one ion pair is found to depend on the velocity of the ionizing fragment.

The gridded ion-chamber technique has also been used to study the alpha spectrum from the break-up of beryllium-8 following the beta-decay of lithium-8. A neutron beam passes through a rotating shutter with equal on and off times of 0·5 sec., and strikes a foil of natural lithium. The delayed alpha-particles are recorded in a thirty-channel 'kicksorter' when the shutter is closed. The alpha-spectrum was studied between 0·5 and 8 MeV., and only the broad excited level of beryllium-8 at 3 MeV. seems to be involved. From a comparison of the total number of delayed alpha-particles, with the number of prompt events from the $^{6}Li(n,\alpha)$ reaction, recorded with the shutter open, a value of 0·042 barn has been obtained for the capture cross-section of lithium-7.

VERTEBRATE PALÆONTOLOGY AND EVOLUTION

A DISCUSSION on "Vertebrate Palæontology and Evolution" was held jointly by Sections C (Geology) and D (Zoology) of the British Association on August 10 at Edinburgh. Prof. T. S. Westoll (Newcastle upon Tyne) began by stressing that only a few selected parts of a very productive field of inquiry could be dealt with at the meeting. Palæontology, essentially a historical and observational discipline, must strive to correlate its findings with the potentially or actually experimental investigations of living organisms.

There is good evidence from the fossil record of evolutionary changes of different orders of magnitude—from phyletic ('micro-') evolution of slow change without extensive reorganization of structural pattern, to adaptive radiations involving the emergence of new structural patterns of divergent adaptive importance. Branches in an adaptive radiation may, after a comparatively short period of relatively rapid divergence, survive through a long period of little further essential change, in which phyletic evolution can often be traced. Adaptive radiations can occur at a great variety of systematic levels, from assemblages of orders (for example, Placoderms) or sub-orders (for example, Perissodactyls) through families (Percoidea) and genera and species (Darwin's finches), probably down to demes. The important question is whether mega-evolution, involving really striking modification of structural pattern, is different in nature.

Orthogenesis is a concept long applied to palæontological series. Closer investigation frequently shows greater complication than was at first thought. Furthermore, the more or less vitalistic or metaphysical language in which orthogenesis is so often befogged is found unnecessary by many recent workers. The imperfect geological record and incomplete fossil remains have contributed to an oversimplification in many evolutionary studies.

In cases of 'macro-' and 'mega-evolution' the fundamental problem is in the stability of structural pattern. Phyletic evolution involves the 'plastic' modification of the same pattern; in the other cases a presumed ancestral pattern has been modified beyond its limits of 'elasticity', so that great modifications and adjustments have been made and then stabilized. In such cases, because of limitations imposed by genetic constitution, development-mechanics and structural factors, independent parallel evolution is not infrequent (secondary palate in Theriodontia, cannon-bones in Artiodactyls, etc.); and the essentially *adaptive* nature of the process is shown by convergence in such cases as Equidæ and Litopterna. Organism and environment each exert 'pressure' on the other; and within the limitations of his field the palæontologist must appreciate this dynamic relationship.

Analysis of some selected case-histories was undertaken by Prof. Westoll, and he showed that the evolution of the horses was not orthogenetic, but that at least three succeeding adaptive offsets have taken place. Factors involved in the radiation of actinopterygian and placoderm fishes were discussed in relation to adaptive modification of pattern. A new analysis of the history of the Dipnoi (a remarkably clear and simple 'mega-evolution' at ordinal level) reveals an integration of finite steps of offset from the early stock, with more-or-less persistent groups settling down at certain stages until replaced by more fully adapted forms. The history of emergence of a major group must be very complex, but there is reason to believe that it took place also by the integration of successive offsets. It was noted that growth-studies are of great importance in this field.

Dr. W. E. Swinton (British Museum, Natural History) reviewed the geological history of dinosaurs, a group usually regarded as diphyletic. The two groups—the Saurischia (large herbivores and bipedal carnivores) and Ornithischia (bipedal and armoured quadrupedal herbivores)—both developed from small, bipedal Triassic Thecodonts. These last had only light armour of bony plates on the back. Though many dinosaurs attained very large size, this is not universal.

Giantism is well shown in the Saurischia. One line culminates in the late Cretaceous *Tyrannosaurus*. The Sauropoda, mainly of Jurassic age, reached some thirty tons in weight, partly compensated by their aquatic habit. The Ornithischia show greater adaptive diversity but less extreme growth in size. Bone-development is often striking. Thus, while the duck-billed *Anatosaurus* (*Trachodon*) has no special outgrowths, late Cretaceous relatives (*Corythosaurus*, *Lambeosaurus*, *Parasaurolophus*) developed remarkable outgrowths of the premaxillaries or nasals or both, which carry the nasal passages and may have served as air-storage tubes during diving. This is an allometric modification of existing bone. Other bipedal Ornithischia (*Troödon-Pachycephalosaurus*) show no excessive growth, but have massive thickening of the frontals and parietals. Brain-casts indicate enlarged pituitary bodies, suggesting acromegalic hyperostosis. The Ceratopsian skull has a characteristic frill of bone over the neck region, with variable development of nasal and supraorbital horns. These are developments of the skull-bones. Again, a large pituitary body is indicated by brain-casts. The relatives of *Stegosaurus* show no thickening of skull-bones, but remarkable plates are found on the body. The pituitary body, so far as known, is small.

It is suggested, continued Dr. Swinton, that very great body size or abnormal bone-development may be hormonally controlled, hereditary and without sex-linkage. Jurassic Saurischia show giantism but no hyperostoses; Cretaceous Ornithischia show hyperostoses but no real giantism. These developments correlate with two widespread Mesozoic temperature minima. This 'phylogenetic pituitarism' suggests that the diphyletic origin of the dinosaurs needs reconsideration.

The relationship between mammals and Synapsid reptiles were then examined by Mr. F. R. Parrington (Cambridge). The Permian and Triassic mammal-like reptiles, especially those of South Africa, first discovered about a century ago, have long been known to resemble Monotremes in their post-cranial skeleton and to develop mammal-like cranial and dental characters. There is general agreement that mammals originated from the later (Triassic) Theriodont members of the Synapsida, but precise origins are obscure. This is largely because of the paucity of fossil theriodonts and mammals from about the end of the middle Triassic through the Mesozoic.

Two upper Triassic skeletons described by Broom showed remarkably close approaches to mammalian conditions, and were placed in the new sub-order Ictidosauria. To this sub-order are now referred a few fragmentary fossils once regarded as advanced Cynodonts, and the remarkable *Tritylodon* and its allies, long regarded as mammals. ***Bienotherium***, a Chinese Tritylodontid, was described by Young, and shown by Watson to retain the reptilian jaw-articulation and to be probably a Cynodont derivative. Kühne has fully confirmed this by his study of the European relative *Oligokyphus* (Rhætic and Lower Lias of Somerset, etc.). The Ictidosauria so defined show a variety of tooth-crown structure.

Certain teeth from Rhætic-Lower Liassic deposits in Britain and Switzerland are still more mammalian in appearance, and suggest comparison both with Symmetrodonts and with Pantotheres, two orders of Mesozoic mammals, the rare remains of which have been fully monographed by Simpson. Two other orders—Triconodonts and Multituberculates—have been regarded as of unknown but separate Theriodont origin, but since then the Tritylodontids, earlier regarded as Multituberculates, have turned out to have reptilian jaw-articulations.

Since there is much diversity of form of the cheek-teeth both in Mesozoic mammals and in Ictidosaurs and other late Theriodonts, and since there is some parallelism, the question arises whether mammals form a true taxonomic unit, or are polyphyletic. The evidence is equivocal, and has been used to defend quite diverse views. But there can be no doubt that many 'mammalian' skeletal features had already been evolved by the Theriodonts. Only the jaw-articulation and middle-ear structures are clear points of distinction. Much of the argument turns on whether such structures are likely to be similarly modified by parallel evolution. The recent important discoveries give hope that palæontology may before long clarify this problem, and perhaps lead to a solution.

Dr. G. S. Carter (Cambridge) also discussed the problem of mammalian origins by focusing attention on the Monotremes, and by using the methods of comparative morphology. The Monotremes are in many respects remarkable structural intermediates between reptilian and mammalian patterns. The phylogenetic position of the Monotremes has been very diversely argued: at one extreme Brazier Howell, on the evidence of the shoulder-girdle, suggests that they evolved from an early reptilian stock quite distinct from that leading to other mammals; at the other, W. K. Gregory recently maintained that they are aberrant marsupials. The most generally accepted view is that they diverged from an early mammalian stock in Triassic or possibly Jurassic times.

The modern Monotremes are specialized: *Ornithorhynchus* is aquatic, and *Echidna* (=*Tachyglossus*) is believed to be descended from aquatic ancestors. Feeding habits are also specialized. Both Monotremes are mammalian in hair, diaphragm, lungs, breathing, heart and blood system, kidneys and most features of skull and jaws. The physiology, so far as is known, is mammalian except in a few characters. Even the small blood-corpuscles are mammalian in form, an adaptation allowing smaller capillaries and a higher metabolic rate. A few characters are worth special attention. Control of body-temperature is by increase of muscular activity when cold; control by sweating is probably absent or slight, and variation of body-temperature with external temperature is greater than in mammals, but less than in living reptiles. Four striking features of Monotremes were noted: the shoulder-girdle retains coracoids and interclavicles, and the fore-limb shows a reptilian posture—it is suggested that in the latter feature *Ornithorhynchus* is adaptively specialized to swimming by means of the fore-limbs, whereas *Echidna* is thought to have had aquatic ancestors; the female generative system is almost entirely reptilian, but mammal-like features are the relatively small yolk and a crude development of a follicular cavity; the monotreme eye is entirely reptilian except for two features, the chief being the superior oblique muscle which turns through a pulley and has moved its attachment area as in mammals; and finally, though facial musculation is developed in Monotremes, a difference from living reptiles, the pattern is different from that in placental mammals.

Monotremes and placental mammals probably diverged when many characters of the soft parts and physiology as well as the skeleton were mammalian, some still reptilian. Most of the monotreme characters are either completely mammalian or completely reptilian: few are intermediate. This implies a series of consecutive changes rather than a grand simultaneous transformation. Such a view is not opposed by the palæontological evidence.

In the ensuing general discussion Prof. Westoll noted that the Theriodonts show several features indicating the piecemeal acquisition of mammalian characters. If one bases classification solely on the presence or absence of the mammalian temporo-mandibular joint, then pouch-young of some marsupials and even an occasional lamb at birth are reptiles.

Lieut.-Colonel L. M. Davies spoke as one to whom evolution is a fact yet to be proved, and pointed out the enormous differences between a bird's feather and any reptilian dermal structures. He asked how such things could happen as a result of explosive evolution. It was pointed out that 'explosive' is a word implying comparative rather than absolute speed of evolution, and that in any case the history of the birds is very badly known. Other speakers discussed giantism in various aspects, and a case of genetically controlled hyperpituitarism was mentioned.

SURVEYS OF UNDER-DEVELOPED AREAS

THE Duke of Edinburgh referred in his presidential address at the British Association to the various shortages which the world is now facing and which are "partly due to the huge inevitable waste of war and its consequences, and partly to the lack of any comprehensive survey of the world's resources and requirements". "It is only," the Duke continued, "by an accurate knowledge of the world's resources that we can foresee the scope and magnitude of the future problems which science and technology have to meet and which only they can solve." For a whole day, on August 14, an inter-section discussion was concerned with the need for the assessment of the resources of those areas that seem to the rest of the world to be undeveloped or under-developed and about which extravagant claims are often made. At the end of the day one of the speakers commented that, from the dozen or so papers read, one thing stood out most clearly—namely, that as scientific men, all recognized the need for more facts. Especially was there a need for the establishment of the facts by preliminary surveys. To make haste slowly was the speediest, as well as the surest, way of developing areas for the benefit both of their inhabitants and of mankind generally.

The importance accorded by scientific workers to the problems of the economic development of the under-developed parts of the world was shown by the number of Sections collaborating—E (Geography), C (Geology), D (Zoology), K (Botany), M (Agriculture) and F (Economics)—and by the size of the audience throughout the morning session. The problem of these areas has been posed by the politicians, notably by President Truman in Point Four of his address to Congress in 1949: "We must embark on a bold new program for making the benefits of our scientific advances and industrial progress available for the improvement and growth of under-developed areas". But it falls to scientific workers to show just how these benefits are to be brought to such regions, and the discussion made it clear that there are no short cuts and no easy solutions, and that a tremendous diversity of conditions must be encountered. Prof. L. Dudley Stamp, who opened the discussion, claimed that the huge losses incurred in the Tanganyikan groundnut and the Gambian poultry schemes showed convincingly that, apart from any possible political or financial mismanagement, there is at present inadequate knowledge on which to base development schemes in under-developed lands, especially in the tropics.

Prof. Stamp explained the purpose and organization of the World Land Use Survey, of which he is director of the Old World Division. He elaborated the aims of this fact-finding survey—to record the existing use of the land and to attempt to ascertain the reasons why the land is used as it is—along lines similar to those of his article in *Nature* of June 23, p. 1010. The need for objectivity, he said, is paramount: if subjective judgments are introduced, the value of such a Survey will be greatly reduced. For these and other reasons, the Survey recommends that any map prepared should be, like the one-inch map, 'survey accurate', even though the final product covering the whole world will be only on the scale of one to one million. The land-use classification drawn up by a Commission of the International Geographical Union is designed to cover as many different categories of land use as possible in regions as diverse and as distant from one another as Thailand, northern Canada and tropical Africa. An essential prerequisite of development anywhere in the world, whether well known and intensively used or unknown and undeveloped, must be a record of the present position and the causes that lie behind it: in Prof. Stamp's phrase, there must first of all be a "synoptic, objective view".

Fifteen years ago the prospects of such a world survey would have seemed meagre indeed, and even to-day the financial problems are large and as yet unsolved. But, as several speakers pointed out, the use of air photographs in mapping now makes possible the covering of much of the world, including many of the under-developed areas. In the absence of Brigadier M. Hotine, the director of Colonial Surveys, Lieut.-Colonel G. J. Humphries described the comprehensive and ever-increasing range of the activities of that Directorate since its establishment in 1946, and discussed some of the difficulties encountered both at headquarters and in the Colonial territories. He explained the adoption of the scale of 1/50,000 as being the one that most nearly meets the requirements of most users of the maps. Contouring remains the chief bottle-neck; hence the issue of 'preliminary plots' in black-and-white only, and with hachuring to indicate certain relief features; but fully coloured, contoured maps will be available later once the immediate and pressing demands of the development plans of all British Colonies have been met. Later in the discussion, Mr. T. D. Weatherhead, director and general manager of Hunting Aerosurveys, Ltd., gave illustrations of how his company's photographs have helped agricultural and planning authorities and guided geologists in undertaking their field-work. He believed that the problem of speedy contouring can be overcome by the wider use of aids such as the airborne profile-recorder.

Two geographers spoke of land-use surveys with which they had been associated and thus illustrated both the potentialities and the problems of so vast a project as a world survey of land use. Dr. J. Wreford Watson, head of the Geographical Branch, Department of Mines and Technical Surveys, Canada, showed how geographers are employed by the

Canadian Government "to survey conditions as they are, . . . geography being regarded as a factual not a remedial aid to government", and described the regional surveys made in different parts of Canada. He pointed out that the size of Canada makes a field-by-field survey impossible and compels the use of the sampling method, larger areas being interpreted by detailed studies of typical samples. In his view the success of the World Land Use Survey will depend on its inclusive categories and its generalized scale. Mr. R. M. Prothero, of University College, Ibadan, described some of the problems of land-use mapping in the forest areas of southern Nigeria, stressing the lack of map-cover in many tropical regions and the difficulties in interpreting air photographs—such as the problem of the identification of cacao, especially in a country with thousands of very small farms. Nevertheless, his preliminary investigations in an area north of Ibadan gave some interesting information that is so often impossible to come by in the tropics, namely, data concerning, for example, bush fallows and the amount of land available for cultivation.

Most of the fields of science concerned in the carrying out of surveys were represented in the discussion, though there was no forestry contribution — an unfortunate omission in view of the breadth of view so characteristic of forestry departments and of individual foresters in many under-developed areas. Prof. T. N. George, of Glasgow, spoke of the geologist's interest in the problems of development. He described how in the past a high proportion of the time of geological surveys was taken up by the investigation of mineral deposits of possible commercial significance, and showed how the question of development still turns largely upon the nature of the economic conditions prevalent at any particular time. The contribution of the soil scientist was emphasized by several speakers, and especially by Dr. Herbert Greene, adviser on tropical soils at Rothamsted Experimental Station. He recognized four factors that have made soil survey easier and more significant during the past twenty-five years: the use of air photography; the concept of soil associations fashioned in East Africa by the late Geoffrey Milne and his colleagues; the discovery of insecticides and drugs that make possible the occupation of vast areas, especially in tropical lowlands, that were not previously available; and the principle of what he termed 'beneficial use', whereby the communal interest and the sense of partnership were seen to matter more than any individual claims to rights in land or water. At the same time, he directed attention to the problems in certain under-developed areas where nationalism seeks the fruits of technology but rejects the foreign technician. He was convinced that the British are right in their policy of encouraging the nationals of such areas to take an active and responsible share in the work of development: thus, and only thus, will they appreciate that the limitations on development are imposed not by the whim of an alien power but by the natural conditions.

"A Zoological Contribution" was the title of Dr. E. B. Worthington's paper, read for him in his absence; but Dr. Worthington speaks as much more than a zoologist, because of his outstanding work for all the sciences in Africa and in virtue of his position as secretary-general of the Scientific Council for Africa South of the Sahara established last year. This Council, an international body, is, he suggested, rightly conceived, since science can know no frontiers, and it would take great notice of this discussion by British scientific men of the problems of under-developed areas. He pointed out how considerable is the scientific potential of Africa to-day, especially on the biological side, largely as a result of wise spending by the metropolitan and Colonial governments and through the establishment of the Colonial university colleges and research institutions in British and non-British territories. The tsetse fly has so far saved much of Africa from disorderly development—in contrast to parts of the Far East and south-east Asia—and in his view there is still time to bring science to bear upon African problems, though he foresaw serious difficulties arising from the rapid growth of population in certain areas.

Most time was not unnaturally devoted to the huge under-developed parts of Africa, but several speakers besides Dr. Watson directed attention to other areas. Miss A. G. Donnithorne spoke of a rather different type of survey, that of the economist. She dealt with the Far East, citing in particular the work done in China by the selection of samples by Prof. Buck and his associates. Dr. C. F. Hickling, fisheries adviser to the Secretary of State for the Colonies, discussed fisheries in all parts of the world and showed that fisheries often represent undeveloped food supplies even in countries that are otherwise well developed many tropical waters are not merely undeveloped but quite unexplored. The Colonial Office is establishing fisheries research stations and fisheries departments which will concentrate on the development of existing fisheries and the improvement of methods of catching and preserving. Care is being taken to avoid the heavily capitalized unit and to enlist, wherever possible, the co-operation of the local fisher-folk. Sir Geoffrey Evans, of the Royal Botanic Gardens, Kew, focused attention on the land settlement problems of those areas round the Caribbean that he knows so well, and where it is hoped that homes may be created in British Guiana and British Honduras for some of the growing populations of the West Indian islands. He stressed the need for preliminary surveys, especially of soils, before the possibility of rail or road construction (essential for any real development) can be entertained. One of the world's basic problems to-day is, in his opinion, that of food supplies in relation to a rapidly increasing population. Contrary to a commonly held view, there are not large areas of first-class land in the virgin tropics capable of producing food: there is, he claimed, far more second-class and marginal land.

It must be recognized, moreover, that not all the under-developed lands are uninhabited, and this in itself gives rise to a whole series of problems. Dr. Greene dealt with the difficulties of partnership, and the several references made by different speakers to human values and relationships made it clear that scientific workers fully recognize their great significance. No speaker put this better than Dr. A. S. Thomas, principal scientific officer of the Nature Conservancy, with a wide experience of tropical Africa. "Development," he said, "is not merely a matter of production and exports, or even of hospitals and schools, but of human development and human happiness. We must preserve this happiness of the people until we know more, not only about their crops, but about them also." Here Dr. Thomas was bringing together the concern of all the sciences. He showed, too, how false are many of the common generalizations about the tropics, and how misleading can be the experience of temperate lands when applied to tropical conditions. We are still grossly ignorant of the interaction of all the factors that control plant growth near the equator, and this information can, he claimed, be gathered in only one way—by the slow, careful, even laborious method of the preliminary, detailed survey. "The more revolutionary the cultural methods to be used," he warned, "the greater the need for pilot schemes and for working in small units."

Statements like these do not appeal to the politician or to the official who wants quick returns and speedy and convincing results. But they are typical of the caution and realism of the scientific worker and, significantly, were endorsed by all those taking part in the discussion. They are clearly the convictions of the organizers of the World Land Use Survey, which will provide an objective record of the existin facts of land use and which is intended as a foundation for schemes of improvement and developmen in all parts of the world. It is to be hoped that small part at least of the many millions at presen available for development and welfare schemes wil be directed towards this Survey in different countrie so that it may speedily be established on a permanen basis. Here is a project in which all the sciences ar interested and all men of science can, and should co-operate: and it cannot fail to make a real an substantial contribution to the scientific study o under-developed, as well as other, areas and also t the progress and happiness of those who are sometime termed the world's under-privileged peoples.

ROBERT W. STEEL

NEWS and VIEWS

Sir Arthur Fleming, C.B.E.

AFTER fifty years of distinguished service to the causes of industrial research and the education and training of industrial personnel, Sir Arthur Fleming has resigned his post as director of research and education to the Metropolitan-Vickers Electrical Co., Ltd., although he will remain a director of the firm; he has also agreed to assume general direction of research and education for the group of electrical firms known as A.E.I., Ltd. The Research Laboratories at Trafford Park, Manchester, which Sir Arthur was responsible for creating and developing, have produced outstanding contributions to scientific and technical knowledge and achievement over a very wide field, and have afforded unique opportunities to a long succession of investigators many of whom have attained eminence in their respective subjects. He will be most remembered, however, for the influence he has exerted on technical education in Great Britain. The number of apprentices and trainees of all grades for whom systematic training has been provided in the Metropolitan-Vickers works now totals more than ten thousand, and a glance through the register of them, published a short time ago, reveals the amazing extent to which these facilities have benefited the electrical industry as a whole, the government services and the educational institutions of the country; and have also provided trained personnel for almost every other country. The Metropolitan-Vickers training scheme acquired a world-wide reputation many years ago, and established a pattern which has been widely adopted.

Sir Arthur's activities have not been confined to Metropolitan-Vickers. His knowledge and experience have been placed unsparingly at the disposal of numerous societies, the universities and government establishments, and, in particular, he has held the positions of president of the Institution of Electrical Engineers and of both the Engineering and Education Sections of the British Association. He has been the recipient of many honours, including the Faraday Medal of the Institution of Electrical Engineers and the Hawksley Medal of the Institution of Mechanical Engineers; he was granted the degree of D.Eng. *honoris causa* by the University of Liverpool; was appointed O.B.E. in 1918 and C.B.E. in 1920 for his work on submarine detection, and in 1945 was knighted for his outstanding services to education. Sir Arthur retains remarkable physical and mental vitality, and it is to be hoped that he will lon continue to give industry and education the benefi of his far-sightedness and intense enthusiasm.

Dr. C. Dannatt, O.B.E

DR. C. DANNATT, who succeeds Sir Arthur Flemin at Manchester, has had some thirty years service wit the Metropolitan-Vickers Electrical Co. After militar service in the First World War, he graduated i electrical engineering from the University of Durha and went to Metropolitan-Vickers in 1921 as a colleg apprentice. He joined the Research Department i 1922 and over many years has built up a very clo association between the Research and Engineerin Departments of the Company on design and relate matters. He is the author of many papers an articles on electrical engineering subjects, and i 1936 was awarded the D.Sc. degree of Durham. I 1940 Dr. Dannatt was appointed to the chair o electrical engineering in the University of Birmingham; but due to war-time commitments he filled i only on a part-time basis. Before and during th Second World War he was actively associated wit the Admiralty in the application of remote contro to gunnery, being one of the original members of th Admiralty Remote Power Control Committee, an for this work he received the O.B.E. in 1943. I 1944 he vacated his university chair and rejoine Metropolitan-Vickers, this time on the electrica engineering side, and became in 1947 chief electrica engineer of the Company with a seat on the Board Dr. Dannatt therefore brings to his new post a ver broad understanding of the requirements of a larg manufacturing organization in industrial researc and also in the recruitment and training of technica staff. Coupled with his additional appointment a assistant managing director of the Company, there i every reason to believe that under his guidance th forward-looking policy of the Metropolitan-Vicker Co. in these vital activities will be fully maintained.

Institute of Biology: Mr. D. J. B. Copp

MR. D. J. B. COPP has been appointed secretary of the Institute of Biology as from October 1. Mr. Copp is a graduate of University College, Southampton, where his studies were interrupted by the War, when he was engaged on radar research at the Admiralty Signals Establishment (Extension), Witley. In 1947 he was appointed assistant secretary of the

British Association and in that capacity he has become well known to a large number of men of science who have greatly appreciated his unobtrusive but active and efficient work in connexion with the five post-war meetings of the Association and with the Association's publications, conferences, press relations, etc. He has taken a special interest in the student membership of the Association and in dealing with applications from school science societies and clubs for assistance in drawing up their programmes. The young Institute of Biology is fortunate to have obtained as its principal permanent official an energetic officer of proved administrative ability.

Physical Society Medal Awards: Dr. A. B. Wood

The Council of the Physical Society has awarded the Duddell Medal for 1951 to Dr. A. B. Wood for his work on the design of instruments for use in work on under-water acoustics. One of the main investigations which Dr. Wood has carried out is the echo depth-recorder, in which magnetostriction oscillators are used for transmitting powerful high-frequency sound signals and to receive weak returning signals. These depth recorders are fitted in many important ships throughout the world, and are adapted to give an automatic record of the contour of the sea-bed over a very large range of depths. The depth recorder was primarily designed for hydrographic surveying and is also used for navigation, the location of wrecks and shoals of fish, and to indicate the silting up of harbours. Dr. Wood was largely responsible for the development of the acoustic mine and for appreciating the difficulties which had to be overcome in ensuring that the explosion of one mine should not actuate the rest of the mine-field. The piezoelectric pressure gauge and cathode-ray oscillograph designed by Dr. Wood are used in investigations of the pressure-time curve of under-water explosions. The details of this work have formed the basis of a large volume of experimental and theoretical research on the damaging effect on ships of under-water explosions.

Dr. J. H. E. Griffiths

The Council of the Physical Society has awarded the Charles Vernon Boys Prize for 1951 to Dr. J. H. E. Griffiths, of the Department of Experimental Philosophy, University of Oxford, for his work on ferromagnetic resonance. In carrying out measurements on the permeability of ferromagnetic materials at centimetre wave-lengths, Dr. Griffiths found that the high-frequency resonance of the metal increased to a maximum with increasing magnetic field and then decreased. This suggested that the effect must be due to ferromagnetic resonance of a nature similar to nuclear resonance; since electron spins precess according to the combined effect of their internal and external fields, this ferromagnetic resonance is capable of becoming a new tool for the investigation of magnetic materials.

Nuffield Foundation Grant to the Royal Anthropological Institute

The symposium on Blood Groups and Anthropology on March 17, 1951, organized by the Royal Anthropological Institute (see *Nature*, May 5, p. 705), served to focus attention on the need for co-ordination of the work now being done in a relatively new field of research. Arising from this symposium, the Institute appointed a Blood Group Committee, and a grant of £14,000 has been made by the Nuffield Foundation to establish a research centre which will be known as the Nuffield Blood Group Centre of the Royal Anthropological Institute. The new Centre will classify the large and rapidly growing body of data on the distribution of the human blood groups throughout the world, assess it statistically and make the results available to anthropologists and other research workers. It will also carry out and stimulate work in Great Britain and abroad where this is desirable in order to follow important clues or to fill gaps in the world picture, and in particular will continue work now in progress on the classification of British blood donors. The centre will be at the Royal Anthropological Institute, 21 Bedford Square, W.C.1, and it is hoped that it will be in operation on January 1, 1952. It will greatly facilitate the work if persons publishing or having published papers on the frequencies of blood groups and other genetical factors in particular populations will send reprints to the Centre. Pending the appointment of a director, reprints will be acknowledged by the Secretary of the Institute.

New Forestry College for Cyprus

A new Forestry College for Cyprus was opened by the Acting Governor (Mr. John Fletcher-Cooke) on September 27. The College, which is situated at Prodhromos, 4,500 ft. up in the Troodos Mountains, is to provide training for forest guards and foresters. In addition to studies in the basic sciences, botany, geology, soil science, meteorology and ecology, the syllabus will include such subjects as sylviculture, crop mensuration, yield regulation, forest engineering and surveying, the utilization and preservation of timber, and protection of forests against disease. Each of the two courses for guards and foresters will last one year. Fifteen places out of a total of thirty-six are reserved for students from countries outside Cyprus, and it is expected that students from neighbouring countries will receive their training there. The director of the College is Mr. R. J. Streets, who was released by the Forestry Commission of Great Britain to take up the post; Mr. Streets was formerly in charge of the Forester Training School, Lindford Hall, Thetford, Norfolk.

Institute of Geodesy, Photogrammetry and Cartography, Columbus, Ohio

The recent establishment of an Institute of Geodesy, Photogrammetry and Cartography in the Ohio State University, Columbus, by the board of trustees, has recently been announced. This embraces an executive board and several committees dealing with research, professional development, etc. An advisory committee of international composition has been appointed by the University administration. In association with the Institute is offered an integrated programme of undergraduate and graduate instruction. The undergraduate curriculum, which covers four years and leads to a B.Sc. degree (with a 'major' in geo-sciences), comprises a broad range of subjects in well-chosen proportion. These, in order of magnitude, are mathematics (a necessary foundation), physics, geology, chemistry, astronomy, etc.; and in the fourth year, geodesy, photogrammetry and electronics. Languages and the humanities have a quarter share of the total programme. The course, indeed, can have a wide cultural value as well as providing a sure foundation for later special study. For this there are graduate courses of instruction suited to individual needs and capacities. Though geodesy is a most ancient science, its applications are much widened by present-century developments, peaceful and otherwise. The scientific surveyor of the second half of the twentieth century requires a wide basic training; and the problem of its provision awaits solution. The trustees of the Ohio State University deserve credit for their constructive effort, and the progress of the new Institute and school will be watched with much interest and may perhaps stimulate similar action elsewhere.

Memoranda of the Indian Science Congress Association

FOUR memoranda prepared by the Indian Science Congress Association, at the request of the United Nations Educational, Scientific and Cultural Organization, have been issued under the title " 'Scicong' Memoranda for Unesco" (pp. 59. Calcutta 16: the Association, 1951). The first of these is a review of the energy and power resources of India, prepared with reference to the Unesco discussion theme for 1950, "World Energy and Power Resources", to which a bibliography is appended. The second memorandum outlines the activities of some typical science clubs in India; these include the students' scientific societies in connexion with universities and like institutions, and some suggestions are made for the further development of such societies, including the use of educational and documentary scientific films and of exhibition boxes of scientific interest. The third memorandum, on the popularization of science through books, gives a fairly comprehensive picture of the position of publication and of science writing in India. Although a start has been made in the popularization of science in India in this way, science writing is unlikely to develop into a professional occupation for some years. The fourth memorandum, on international collaboration between existing associations for the advancement of science, reviews briefly the history of the Indian Science Congress Association and discusses the desirability of forming an international federation of associations for the advancement of science. One reason for advocating the formation of such a federation is that it might deal more satisfactorily with questions relating to freedom of scientific inquiry, and the dangers involved by secrecy in science, than the Committee of Social Relations of the International Council of Scientific Unions has done. The value of that Council for purely academic and scientific problems is fully recognized; but the Indian Science Congress Association would welcome the formation of a federation to encourage symposia and discussions of scientific problems of wide social and international import and the publication of an international journal covering such matters.

Survey of the Ticks of South Africa

THE *Onderstepoort Journal*, created in 1933 to replace and continue the annual reports of the director of veterinary services and animal industry of the Department of Agriculture, Union of South Africa, has earned a permanent place in all libraries that cater for readers interested in the welfare of domesticated animals, the diseases that afflict them and the organisms that cause these diseases. The papers it publishes reflect the wide scope of the work done at the Onderstepoort Veterinary Research Station, from which the *Journal* is published. A feature of this work has always been its broadly biological outlook. Typical of this is the survey of the ticks of South Africa, which has been undertaken as part of a zoological survey of the Union. Ticks collected all over the Union by government veterinary officers have been sent to the Onderstepoort Laboratory, and the material thus collected is being studied by Miss Gertrud Theiler. In Part 1 of her report (*Ond. J.*, 23, 217; 1948 [*sic*]) she comments on the difficulties created by the methods adopted for the collection of the ticks. She has, however, been able to draw certain conclusions from her studies. The species discussed by Miss Theiler are as follows: in Part 1, *Amblyomma hebraeum*, the vector of 'heart water'; in Parts 2–3 (*Ond. J.*, 22, 255; 1949 [*sic*]), *Boophilus decoloratus*, the blue tick, and *Rhipicephalus appendiculatus*, the brown tick; and in Parts 4–6 (*Ond. J.*, 24, 1; 1950), *Rhipicephalus capensis*, *R. evertsi*, and *Ixodes pilosus* and *I. rubicundus*. Each of the articles is accompanied by maps which show the localities in which each of the ticks discussed was present, together with information about the nature of the districts concerned and about the relevant climatic factors.

Prehistoric Sites on the North Cornish Coast

A VERY useful article entitled "Prehistoric Sites on the North Cornish Coast between Newquay and Perranporth", by Joan R. Harding (*Antiquaries J.*, 30, July–October 1950), deals with a coastal area of Cornwall which is a little more restricted than is indicated by the title and covers the coast from Kelsey Head to the Penhole Sands. At the former site Mesolithic and Iron Age finds have been made, and at the latter relics of the Mesolithic and Bronze Ages have been discovered. Judging from the illustrations, the Mesolithic finds recall those made farther north at Constantine Bay near Padstow. Culturally, the flint industries are undoubtedly Mesolithic, though in time they may well be later and even overlap with the early metal age. Miss Harding is to be congratulated on bringing forward some very interesting finds.

Scottish Postgraduate Agricultural Scholarships

THE Department of Agriculture for Scotland has recently awarded postgraduate agricultural scholarships, commencing this year, to the following. *Husbandry*, N. H. Cuthbert (Glasgow), dairy husbandry at the University of Reading; A. F. Gristwood (Edinburgh), poultry husbandry at the University of Edinburgh; P. C. Harper (Aberdeen), rural science at the University of Edinburgh; A. M. MacNair (Glasgow), agriculture at the University of Cambridge; I. S. Robertson (Edinburgh), agriculture at the University of Cambridge; T. Webster (Glasgow), agricultural science at the University College of Wales, Aberystwyth; *Agricultural Economics*, H. C. Currie (Edinburgh), agricultural economics at the Agricultural Economics Research Institute, Oxford. Three current awards have been extended for a further period of study as follows: *Husbandry*, A. O. Ballantyne (Glasgow), Ph.D. degree at the University of Edinburgh, H. G. Livingston (Aberdeen), dairy husbandry at the University of Minnesota; *Statistics*, St. C. S. Taylor (Edinburgh), Ph.D. degree at the University of Edinburgh.

ERRATUM.—In the article "Britain's Scientific Shrines (6)" in *Nature* of September 15, p. 443, column 2, for "Dr. William Browning" read "Dr. William Brownrig".

SLOW-NEUTRON TERNARY FISSION OF URANIUM-235

By PROF. E. W. TITTERTON
Australian National University

THE liquid-drop model of the fission process[1] was used by Present[2] in 1941 to predict that fission into three charged fragments is dynamically possible. A mode of fission involving three charged fragments was observed by Alvarez in 1943 in the case of the slow-neutron fission of uranium-235. Since that date, there has been a considerable body of work on the subject[3].

Experiments using photographic plates have been made by Wollan *et al.*[4], Demers[5], Green and Livesey[6], Tsien *et al.*[7] and Marshall[8]. They indicate that in about one-third per cent of the cases the slow-neutron fission of uranium-235 gives rise, in addition to the two heavy fragments, to a long-range α-particle which is emitted at nearly 90° to the heavy fragments. In these experiments the number of events with long-range light fragments were few, being respectively 27, 6, 58, 30 and 80, and many of these were incomplete, the long track leaving the emulsion. Moreover, except in the cases of Demers and Marshall, the emulsions employed were insensitive to energetic protons.

During three years work at the Atomic Energy Research Establishment, Harwell, detailed experiments were carried out using Ilford C_2 and D_1 emulsions impregnated with a saturated solution of uranyl acetate and irradiated in slow-neutron fluxes in GLEEP and BEPO. These experiments had as their objective: (1) Determination of the possibility of proton emission at the instant of fission. (2) Investigation of possible negative proton emission as an alternative to the delayed neutron emission known to occur from certain fission products. (3) Study of the energy distribution, angular distribution and frequency of the α-particles known to be emitted. (4) Search for the emission of heavier nuclei. In particular, lithium-8, or boron-8, either of which would give rise to a 'hammer track'[9], or beryllium-8, which would give rise to two α-particles. Examples of beryllium-8 emission have been observed by Goward, Titterton and Wilkins[10] in the photofission of uranium and by Titterton[11] in the fast neutron fission of thorium-232. (5) Determination of the frequency of occurrence of fission into three equal fragments, one case of which was reported by Tsien *et al.*[7].

More than half a million fission tracks have been examined, about half in C_2 emulsions sensitive to protons up to an energy of 40 MeV. and half in D_1 emulsions which, under the conditions of the experiment, recorded α-particles well but protons only up to an energy of 2·5 MeV. More than a thousand cases of ternary fission were observed, and preliminary results were reported briefly at the 1950 Harwell Conference[12]. The main results may be summarized as follows:

(1) Protons associated with fission tracks were observed in the emulsions. Where these were of range greater than 20 μ (1·25 MeV.) it could be shown from the geometry of the event that the track was due to a proton knocked-on by one of the moving fission fragments. Such protons, therefore, were not associated with the fission process.

(2) Negative proton emission was not observed, and if it occurs at all, is an improbable process. An upper limit of 1 in 5 × 10^3 can be assigned to the probability of negative proton emission relative to delayed neutron emission from the fragments concerned. This is discussed in detail elsewhere[13].

(3) The long-range α-particles emitted in fission are found to have an energy distribution as shown in Fig. 1, which is based on 862 complete events. The most probable value of the energy is 15 MeV., but the distribution extends to a maximum value of 29 MeV. This maximum value is considerably greater than that given by early workers—Farwell *et al.*, 16 MeV.; Green and Livesey, 20 MeV.; Tsien *et al.*, 25 MeV.; Wollan *et al.*, 22 MeV.; Marshall, 26·5 MeV.; Allen and Dewan, 26 MeV. The angular distribution of the α-particles relative to the light fission fragment is shown in Fig. 2, and from its shape definitely precludes the possibility, suggested by Feather[14], that the α-emission might take place from one of the moving fission fragments, or the possibility that a (n,α) reaction is followed by fission. The observed maximum α-particle energy is consistent with the idea that the α-particle is left between the two heavy fragments and acquires its energy from their electrostatic fields. The angular distribution also supports the view that the α-particles, in most cases, are left at rest and acquire their energy by repulsion from the heavy fragments.

The energy released in this mode of fission was measured and, within the limits of the experimental errors, was found to be the same as for binary fission.

For three-particle events with α-particles in the energy range 5–30 MeV., the frequency of occurrence was found to be 1 event per 422 ± 50 binary fissions, a figure which compares with 1 in 505 ± 50 for the same energy-range found by Allen and Dewan[3] in the most recent counter experiment.

(4) In the present investigation, no instance of lithium-8, boron-8 or beryllium-8 emission has been observed. However, in agreement with other authors[6,7], short-range fragments, apparently associated with the fission instant, were observed. By plotting the frequency of occurrence of recoils along the fission track, it was shown that there is an excess of tracks in the central region over that to be

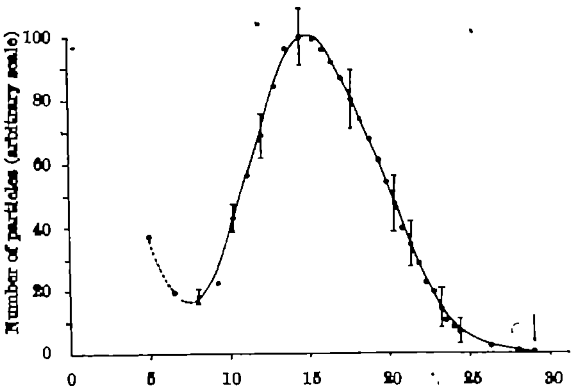

Fig. 1. Energy spectrum of the α-particles emitted in the slow-neutron ternary fission of uranium-235. The arrow indicates the energy of the most energetic particle observed

Abscissa. Angle (degrees) measured from light fission fragment.

expected from the theory[16]. Moreover, work with desensitized emulsions showed that these tracks were still present when the emulsion was no longer recording α-particles. These experiments suggest that at least some of these short-range particles have a charge greater than 2, and tracks of this class were found with ranges up to 5 cm. of air[10], though the most probable value was observed to be ~ 1 cm. of air. After correction for random events caused by the chance superposition of fission tracks on the background of α-particles and protons (from the reaction $^{14}\mathrm{N}np^{14}\mathrm{C}$) which are present in the emulsions, a frequency of occurrence for these events can be obtained. Three-particle fission, in which the light fragment has a range less than 20 μ, was observed at the rate of 1 event per 85 ± 10 binary fissions. This frequency is in agreement with that found by Green and Livesey and Tsien *et al.*, while the indication of fragments of Z greater than 2 is supported by recent counter experiments of Dewan and Allen[15].

(5) Although events comprised of three heavy fragments each of range greater than 5μ were observed in the emulsions, the geometry in all cases was compatible with their being formed by the collision of the fission fragments with silver and bromine nuclei in the heavy component of the emulsion. Moreover, the frequency of occurrence of these events was as predicted theoretically, assuming the interaction to be with the silver and bromine nuclei in the emulsion.

The experiments thus provide no evidence for fission into three approximately equal fragments as originally suggested by Present[2], and, in this respect, confirm the counter experiment of Rosen and Hudson[17]. The event observed by Tsien *et al.*[7] in which a particle of mass ~ 32 was emitted must therefore be regarded with suspicion, since if it were true ternary fission some fifty such events should have been observed in the present experiments.

A detailed account of these experiments is in preparation and will be published at a later date. Thanks are due to the ten microscope observers who, in the course of their training, worked on the problem with great diligence, and especially to Miss E. M. Chellingworth, who helped with the analysis. I am grateful to Sir John Cockcroft, director, Atomic Energy Research Establishment, Harwell, for permission to publish these results.

HIGHER EDUCATION IN BRITISH COLONIAL TERRITORIES

THE report on measures for the economic development of under-developed countries, which has recently been issued by the United Nations Department of Economic Affairs, stressed the difficulties which the low level of technology in such countries present to their development. One major obstacle to the advance of technology in such countries is the absence of an educational and administrative structure through which the producers can learn technology. Even where leaders of such a country at various levels—politicians, teachers, engineers, business leaders, trade unionists, religious leaders, journalists—all desire economic progress, understand what is required, and are willing to pay the price, much will still depend on education. The preparation, as recommended in this report, of a programme of education and research for a period such as five years, indicating not only objectives and proposed expenditure, but also what is required for agricultural extension services, for industrial training, and for the training of scientific workers and administrators, will make considerable demands, in both its preparation and execution, on the services of trained minds in such countries.

It is in the light of such ideas and plans that the significance of the work of the Inter-University Council for Higher Education in the Colonies is best assessed to-day. The third report of the Council*, which covers developments since September 1949, is thus appropriately considered against the background provided by the general survey over roughly the same period provided by the current report "The Colonial Territories, 1950–51"†, in which due weight is given to those political developments in self-government, for example, in the Gold Coast and Nigeria, which are making in themselves such demands on wise leadership by educated men and women. Those developments are summarized in Chapter 2 of the report, while the broad background of the educational situation is reviewed at the outset of Chapter 5, dealing with social services.

A feature of the report on "The Colonial Territories, 1950–51" is the evidence it supplies of the extent to

† The Colonial Territories, 1950–51. Pp. ix+184. (London: H.M. Stationery Office, 1951.) 4s. 6d. net.

which the people of these territories are learning to increase their own revenues through a better use of their natural resources, to meet the many and varied professional and technical needs of their own countries—in medical and health work, in industry and commerce as well as in social services of all kinds, including education—and to acquire the art of government through participation in their own political institutions. Much yet remains to be done. It is early yet to judge the success or otherwise of the constitutional developments in the Gold Coast, Nigeria and elsewhere, and both in health and in education there are serious shortages of staff which limit developments.

Nevertheless, the expansion of education, despite this and the other main limiting factor—finance—is again encouraging. In Malaya, the number of children at school increased by 50,000 during the year, and in Hong Kong, where seventy-three new schools were opened, by 30,000. In Kenya a scheme has been approved for raising the standard of African education at an estimated annual cost of £966,000 and a capital outlay of £1¼ million over the next five years; Nyasaland has completed a survey of schools as a basis for a detailed programme of development to be completed in 1954; and in Tanganyika the 'ten-year plan' has been revised to provide primary schooling for a much larger number of African children. All territories, however, are still hampered by a serious shortage of teachers, although local training facilities and their output are increasing and there is a large recruitment of teachers from the United Kingdom each year. In Nigeria, for example, there are now eighty-eight teacher-training centres, including twenty-two for women, and two rural education centres for training teachers in rural science. Education for girls is a sphere in which expansion is particularly important.

The exchanges between the United States and the Colonial territories under the Fulbright scheme, and the research work and surveys briefly summarized in this report make special demands on the trained men and women coming from the Colonial universities. Travel grants have already been approved under the scheme to enable thirteen candidates from Malaya, Singapore, Nigeria, Kenya and Uganda to visit the United States for study and research. Meanwhile, progress in starting the various Colonial research stations and institutes is frequently hindered by the shortage of qualified staff.

There are now three universities and five university colleges in the British Colonial territories and the Anglo-Egyptian Sudan, and of these the University of Malaya was founded in October 1949, Makerere College achieved university college status in November 1949, and in February 1950 the University College of the West Indies installed its first chancellor. These eight institutions, according to the third report of the Inter-University Council, have a total of 3,056 full-time students, the University of Malaya having 791 students in the current session and the University of Hong-Kong 715, while in the 1949–50 session there were a further 4,014 Colonial students in the United Kingdom, of whom 1,745 were in universities and university colleges. The total has increased to about 4,500 in the current session, the proportion of university to non-university students being probably the same. Since in 1951 the minimum requirements for entrance to United Kingdom universities are being raised, the number of Colonial students qualified for admission will decrease, and the need for developing the Colonial universities and colleges and completing their building programmes will become the more urgent. The situation is now developing in fact in which a Colonial student will normally proceed overseas only for postgraduate and specialist courses or for courses not provided locally.

Excluding the Royal University of Malta, where much of the teaching is undertaken by part-time staff, there are now in the remaining institutions 130 professors or heads of departments, 24 readers or senior lecturers, 144 lecturers, 90 assistant lecturers and 69 part-time specialist staff (chiefly in the faculties of medicine) as well as 15 full-time staff in the extra-mural departments. The student/staff ratio varies considerably, from 8 at Hong-Kong to 28 at the University College of the Gold Coast; but the extent to which academic staffs of high qualifications have been recruited induces the Council to hope that it will invariably be possible to maintain a generous staff/student ratio, both because of the special teaching problems inherent in Colonial higher education and also because it is essential that the staff should have adequate time for research. It is also encouraging to note that the proportion of locally born staff is rising.

A feature of the latest report on Colonial research was the evidence of the close association in the Colonies between research and higher education, and during the year the Inter-University Council learned from the Colonial Research Council that the mutual advantages of such an association are fully recognized. The main volume of research at the Colonial university institutions, however, is the private work of the academic staff, and already this output from some five hundred specialists represents a substantial addition to the resources of science and scholarship. Its value should be enhanced by the Fulbright scheme already mentioned, for under that scheme American professors, research workers and students are enabled to work in Colonial institutions; during 1950–51 there were twelve such academic guests at the Universities of Malaya and Hong Kong and the University Colleges of the West Indies, Gold Coast, Ibadan, and Makere.

While progress in building schemes is extending the laboratory facilities which make the Colonial universities and colleges attractive as centres for research, and on the financial side these institutions are receiving generous local support from governments as well as from private organizations and individuals, appreciable progress is also reported in the libraries of all these institutions—in their holdings, administration, staffing and services. Again, particularly at the Colleges in the West Indies, the Gold Coast and Ibadan, extra-mural departments have been well developed, while all five university colleges are in a special relationship with the University of London to assist them to establish their standards and to devise the curricula and syllabuses for the degrees which they will award when strong enough to assume independent university status. Under this scheme, moreover, the University has made a separate arrangement with each of the colleges to meet the problem of entrance requirements and matriculation arising from the introduction by the Home Universities in 1951 of new minimum requirements for admission. The Council also welcomes the establishment in October 1949 of the Advisory Committee on Colonial Colleges of Arts, Science and Technology, and has held joint meetings with this advisory committee to discuss engineering education. Three such colleges have been established, in Nigeria, the Gold

Coast and Sierra Leone, and one of their most important functions will be to teach technical and commercial subjects up to professional level and to increase facilities for teacher training.

Technical education at the lower levels is, in fact, receiving increasing attention everywhere in the territories: in Uganda the main educational effort is towards schools of a less academic type; the junior technical schools in Malaya are filled to capacity, while a course in architecture has been added at the Technical College in Kuala Lumpur, and building for a new technical college is about to commence.

All these developments involve demands on the Colonial universities and university colleges and affect their work as well as the prospects for their students. But while the Inter-University Council has clearly been considering a wide range of problems as well as the factual developments recorded in this report, it scarcely touches on some fundamental issues concerning the position of university institutions in Colonial society. Satisfied that adequate academic standards of work have been attained and are likely to be maintained, the Council does indeed recognize that it is now becoming important to ensure that the most effective use is made of the services of students trained in such institutions, from the point of view of the students themselves and of their peoples. But it contents itself with expressing the hope that too high a proportion of the graduates will not be absorbed into government service, because of the importance of introducing some of this sure experience and trained ability into other sectors of society, such as journalism, commerce and industry.

The future of the Colonial universities does not depend solely on their ability to maintain high academic standards: it depends equally on their ability to provide the societies which they exist to serve with trained men and women who can meet the needs of these societies and fit happily into their way of life. If there is no place in such societies for the men and women coming from the new university institutions, no opportunity for the utilization of their technical or professional ability, and no adequate or satisfying cultural life, those institutions will themselves ultimately decay. The absorption of trained man- and woman-power into the Colonial life of to-day involves difficult and interesting problems, and the Inter-University Council could appropriately have used its annual report to discuss one or two such topics, particularly those bearing on the relationship between university education and secondary or primary education.

CURRENT TRENDS IN SOCIAL PSYCHOLOGY

At the recent Edinburgh meeting of the British Association, Section J (Psychology) devoted each of its five mornings to current trends in psychology, and in one session, "Current Trends in Social Psychology", four papers were presented which had many interlocking features. The first, by Dr. H. J. Eysenck, described researches into social attitudes. He held that popular newspaper polls of public opinion, the Gallup and similar polls, though interesting, are of little scientific value. Newspaper polls ask broad, general questions, and do not take sufficient account of the political affiliations of people questioned. Investigation into attitudes towards different issues of present-day importance show a great tendency for certain attitudes to cluster together in a manner characteristic of Radicals and Conservatives.

Dr. Eysenck propounded a distinction between what he calls "tough-minded" and "tender-minded" persons. (It is perhaps unfortunate that this distinction, well known in psychology since the late Prof. William James first used these terms, has been accepted by psychologists as meaning something different, but not entirely different, from Dr. Eysenck's new use of the term.) He contrasted the moral approach of the tender-minded, who are idealistic, ethical, religious and to whom the individual is sacrosanct, and the tough-minded, who believe in the inferiority of coloured people, Jews and women, and in the 'inevitability' of war. The working-class person, he said, is on the average very much more tough-minded and conservative than the average middle-class person. He described recent investigations into the organization of attitudes, their relation to political-party membership, age, sex, education, social class, and personality, and also into the effect upon the structure of attitudes of differences in culture-pattern.

The second paper, on "Personality Tests as Research Tools", by Dr. Hilde T. Himmelweit, considered 'objective' tests that require the subject to perform some task under standard conditions, the response to which can be objectively measured. Examples of these tests are of motor co-ordination, speed and accuracy of response, suggestibility, persistence, levels of aspiration and expressive movement. Though the behaviour involved in these may throw light on deeper mental levels, such tests do not tap these levels as specifically as projection tests do, and yet the results of objective tests are unaffected by the psychologist's subjective interpretation of the responses.

The use of batteries of objective tests makes possible the investigation of entirely new problems. One concerns the relationship between normal, neurotic and psychotic states. Kretschmer has maintained that these conditions differ from each other only quantitatively, not qualitatively, and can be viewed as lying along the same continuum with schizophrenia and manic-depressive psychosis. Eysenck, using a wide range of objective personality tests, has found that, on most tests, the patterning or inter-correlations of the test result was sufficiently similar in the normal and psychotic groups to support strongly Kretschmer's hypothesis. Objective tests are also useful in studying the effect upon the personality of leucotomy. Asenath Petrie has given tests to patients before and at stated intervals after this operation. The results enabled her to describe the characteristics of the post-leucotomy personality.

Objective tests will be used in a research, being carried out at the London School of Economics, into the differences in attitude to personality characteristics of young adolescents from different social classes. They will test the hypothesis proposed by Davis, of Chicago, that middle-class parents cherish higher aspirations for their children than working-class parents, that the child tends to introject the parents' demands and to react by having higher aspirations and being anxious regarding their attainment. It is proposed to find the extent to which middle-class children, compared with children from other classes, give significantly higher scores on tests of 'level of aspiration' and of anxiety.

The next speaker, Dr. A. T. M. Wilson, discussed "Social Changes in Structured Groups", a group being termed structured when it contains a manifest system of inter-related roles. The study of social processes in real (that is, not artificially created) situations, in terms of the psychological and social forces concerned, raises problems connected with the possibility of obtaining access to the group for the purpose of direct observation. There may be resistance or reluctance to proposals that the social investigator should be admitted to a 'reality situation', and this raises questions concerning the role of a participant observer in a community particularly susceptible to social change. If in a structured group need is felt for help in bringing about desired change, this need will provide one set of circumstances facilitating access by the investigator. A research worker, responding to a request for technical collaboration, in tackling a group problem, may assume a role the existence and independence of which are derived from its responsible professional character. The use of such roles may facilitate social change, since insight, derived from observations equally available to the group concerned and to the research worker, can be mutually communicated. The scope and limitations of such an approach were illustrated in detail from the work of one industrial organization which employs it.

Prof. T. H. Pear discussed "The Social Psychology of Everyday Life". This paper's title, borrowed with grateful acknowledgment, is that of a well-known article by Prof. Hadley Cantril, of Princeton University[1]. Written seventeen years ago, it urged that really important events in the lives of ordinary people had seldom been studied by psychologists.

To-day, one can report a considerable increase in the social significance of the subjects studied. The development of techniques for investigating attitudes and public opinion and for interviewing (for example, in vocational guidance, medicine and anthropology), the study of likenesses and differences in national characteristics and the effect of social factors upon test performances, the intensive study of patterns of culture and tensions between communities[2], all these events and more testify to a considerable change in the climate of opinion. The ordinary man in his social setting here and now is gradually if slowly becoming an object of scientific interest.

There are still important subjects which have received relatively little attention from social psychologists. Of these the most obvious are peace and war, since to-day almost all problems of planning are affected by the possibility of another war. Another neglected subject in Britain is social stratification. To the study of these subjects there certainly exist strong resistances; to discover and account for them is an interesting task for the social psychology of the future.

Prof. Pear's paper suggested that discovering the causes of this oversight is an interesting psychological project. Consider differences in classes, strata and *élites*. Much has been written about inferiority complexes[3], and our knowledge in this realm would be enriched by introspective accounts of how it feels to find oneself in such 'natural' situations of superiority or inferiority, and of the modifications of behaviour which one deliberately produces to adjust oneself. Partly conscious, partly unconscious factors may cause the widespread lack of interest among psychologists in problems of peace and war and of social stratification. It is time to realize frankly that in many people there are conscious reasons for not objecting to war. Unconscious reasons exist too; but they have had a good Press for the past three decades, and more research into the conscious reasons is needed. It is time for students of society to direct public attention less to the differences between peoples and much more to their resemblances, even if this decreases the 'novelty-rarity' value of their books and lectures.

During the meeting a demonstration was given of a film-gramophone technique, devised by Davide Boulting, C. E. M. Hansel and Prof. Pear, to investigate impressions of personality, vocation and social stratum from voice and facial appearance. While a voice spoke a prescribed passage designed to bring out geographical or social 'accents', pictured 'backgrounds', both physical and social, and faces were projected on the screen. In the experiments to be carried out, subjects will attempt to match these with the voices.

RECENT DEVELOPMENTS AND TECHNIQUES IN THE MAINTENANCE OF STANDARDS

A TWO-DAY symposium was held at the National Physical Laboratory during May 21 and 22 on "Recent Developments and Techniques in the Maintenance of Standards". Most of the standardizing laboratories of Europe, the Commonwealth and North America were represented, and delegates attended from many research organizations and industrial firms in Great Britain. Dr. E. C. Bullard, director of the Laboratory, in opening the symposium, remarked that it had every chance of being a successful occasion since there was no official business of any kind and no one need come to any conclusions. Sir Ben Lockspeiser, secretary of the Department of Scientific and Industrial Research, was among the audience and added his welcome to Dr. Bullard's.

Dr. D. G. Sopwith, superintendent of the Engineering Division of the Laboratory, took the chair for the first session, on "Primary Load Standards". The first paper was presented by Mr. B. L. Wilson, head of the Engineering Mechanics Section of the National Bureau of Standards, Washington. He gave a very interesting summary of the various dead-weight machines belonging to the Bureau and the types of devices calibrated in them. Dr. F. Aughtie (National Physical Laboratory) followed this with a paper on "The Primary Load Standard" in which he described the 50-ton dead-weight standard at the National Physical Laboratory and spoke of the adjustment of it to 'standard' gravity (980·665 cm./sec.), which was about to be undertaken. He described also the Laboratory's 5-ton standard for the calibration of small proving rings, and experiments with resistance-strain gauges on compression elements for loads greater than 50 tons.

The second session was concerned with "The Standard of Length", and Mr. F. H. Rolt, superintendent of the Metrology Division, National Physical Laboratory, was chairman. The first paper, "The Present State of a Lightwave Standard of Length", by Dr. E. Engelhard (Physikalisch-Technische Bundesanstalt, Brunswick), was presented for him by Mr. H. Barrell (National Physical Laboratory) in the form of a summary. It was pointed out that for more than twenty years, industrial end-gauges have been calibrated by reference to wave-lengths of light, and at the same time investigations have continued to find the best light sources. The pure mercury isotope ${}^{198}_{80}$Hg and the krypton isotopes ${}^{84}_{36}$Kr and ${}^{86}_{36}$Kr are now available for the excitation of an optical wave-length standard of great accuracy.

The method developed by Kösters at the Physikalisch-Technische Reichsanstalt (now the Physikalisch-Technische Bundesanstalt) for comparing wave-lengths of light with the metre has some interesting features, first in the use of a new type of beam divider, the 'interference double prism', secondly in the direct absolute interferometric measurement of an industrial 500-mm. end-gauge by means of Fizeau's fringes and the subsequent direct comparison of the end-gauge with an *Endstrichmeter* (a line metre which is also an end-gauge), and thirdly in the elimination of the refraction of air by means of a vacuum chamber.

The question whether a light-wave standard ought to be defined by wave-length in air or *in vacuo* was discussed. Kosters's method of eliminating the refraction of air removes the objection to a vacuum wave-length standard that in practice all measurements (for example, of block gauges) would be made in air.

The relative advantages of the mercury isotope and the krypton isotopes as sources of light were discussed, and the use of the krypton lamps at the temperature of freezing nitrogen was described. Experiments using xenon instead of krypton have so far not met with success. Various manifestations of line broadening and line displacement were discussed, and the essential conditions were specified for eliminating self-reversal and asymmetry of lines, which would lead to errors in the use of a light-wave standard.

It is not possible at present to realize an ideal light-wave standard. Lines emitted by an atomic beam would be ideal theoretically, but the intensity is too low. The question now is whether a mercury or a krypton isotope should be used to define the new standard of length.

Mr. Barrell then read his own paper, "The Interferometry of Length", in which he began by summarizing the history of the spectroscopic reference standard, the red line of cadmium, with the events leading to the present use of the mercury isotope ${}^{198}_{80}$Hg and the krypton isotopes ${}^{84}_{36}$Kr and ${}^{86}_{36}$Kr. He reviewed the progress of the investigations to select a wave-length to serve as the ultimate standard of length.

For the mercury isotopes, a simple form of electrodeless discharge lamp, free from certain broadening effects, has been designed at the National Bureau of Standards, Washington, by Meggers and Westfall. A series of well-distributed wave-length standards reproducible to ± 0·0001 A. has been provided from the isotope ${}^{198}_{80}$Hg; these standards have recently been used at the National Physical Laboratory for testing the accuracy of a new dispersion equation for air, valid over the range 2500–6500 A.

In Great Britain, various types of mercury-198 discharge lamps are now being produced commercially by the General Electric Company, Ltd. At present, the electrodeless lamp with 3 mm. argon is the best source of mercury-198 standards, but it has been established at the National Physical Laboratory that the argon produces slight asymmetrical broadening of the mercury-198 lines, the consequent red shift in the visible spectrum amounting to 0·0001 A. (−0·0003 cm.$^{-1}$) per mm. of argon. The amount of argon in the lamps must therefore be controlled with 0·5 mm. mercury pressure to ensure reproducibility of wave-length within 1 part in 10^8.

The direct measurement of length by interferometry is now generally applied whenever the utmost precision and reliability are required. A specially designed form of Fizeau interferometer at the National Physical Laboratory will accept for measurement at one time up to twenty block gauges of size 2·5 cm. or less.

At the National Physical Laboratory, experiments in the measurement of distances of several metres are being made with electromagnetic waves of radio-frequency, using an interferometer of a modified Michelson form; a stabilized klystron source generates microwaves of frequency 24,000 Mc./s. (= 1·25 cm.). The velocity of radio waves may be determined by reversing the process employed.

In answer to a question as to whether the refractive index of air was known to the accuracy demanded for interferometric work, Mr. Barrell said that wave-length measurements made in air can now be reduced to the vacuum condition (or vice versa) with a reliability of 3 parts in 10^8.

For the afternoon session, on "Standards of Radioactive Isotopes", Dr. B. W. Robinson, superintendent of the Physics Division, National Physical Laboratory, took the chair, and Mr. R. C. Hawkings (Atomic Energy Project, National Research Council of Canada, Chalk River, Ontario) read the first paper, prepared by himself, W. F. Merritt and J. H. Craven, on "The Maintenance of Radioactive Standards with a 4π Proportional Counter".

There is a need for instruments by which the absolute rates of disintegration of atoms can be directly measured, and there are many advantages in a particle counter having a solid angle of 4 steradians with the source. The workers at Chalk River have constructed a spherical 4π counter, which Mr. Hawkings described in detail. Each of the two sections consists of a hemispherical brass cathode having an anode connexion passing through a plastic insulator in the apex. The operation of the counter was described, with the type of amplifier made necessary by the wide distribution of pulse heights originating in it. The type of plateau obtained and the linearity up to 3×10^4 counts per second are very satisfactory.

The efficiency of the 4π counter is reduced to some extent by absorption losses in the source mount and self-absorption of the source itself. The losses in the mount, however, can be minimized by using the thinnest possible film; the correction is determined by placing an identical film over the source and then applying the reduction in count as a correction to the original count. Film-absorption correction factors for some commonly used nuclides were listed. The elimination of self-absorption losses was also discussed.

The relative regions of maximum efficiency using various counter gases were discussed, and the stability and reproducibility of the counter. The limiting factor in attempts to increase accuracy now seems to be the technique of preparation of the source. Results obtained with the counter were compared with those derived from other methods, for example, defined solid angle and coincidence, for various nuclides.

The counter described, while sturdy and easily and quickly decontaminated and reassembled, is nevertheless a precision instrument which, when used in conjunction with the coincidence method of counting, has already proved invaluable in Canada and the United States.

The second paper of this session, by Mr. W. E. Perry (National Physical Laboratory), dealt with "Standardization of Radioactive Isotopes by Coincidence and γ-Ray Ionization Methods". Pure specimens of artificial radioactive isotopes in weighable quantities are not available; hence it has not been possible to prepare gravimetric standards as with radium. Standardization therefore requires activity measurements. At the National Physical Laboratory three methods have been used: β-particle counting by the small defined solid-angle method, the (β–γ) coincidence method and the γ-ray ionization method. Mr. Perry's paper was concerned with the last two.

In the (β–γ) coincidence method, the elementary formula for the disintegration-rate was derived, and the modifications to it to allow for various types of unwanted coincidences were discussed. The method requires two separate counting measurements and the measurement of the resolving time of the coincidence circuit, and the techniques of these were described. In particular, the introduction of an absorption screen, used to separate β- from γ-counts, is open to argument.

Results of the measurements of six cobalt-60 sources were given, in which the accumulated total error is thought to be at least ± 2 per cent.

The γ-ray ionization method was also briefly described. This is based on the relationship between ionization and the γ-ray energy: a value may be derived for the ionization produced by γ-rays from a given quantity of a radioactive isotope if certain fundamental constants can be assumed. Results were given of comparative measurements using both the coincidence method and the ionization method; the uncertainty in the ionization values is believed to be about ± 4 per cent and the differences between the ionization and coincidence values do not exceed this. Activity values for isotopes reported by various institutions in Great Britain reveal differences of the same size, and investigation must continue so that reliable standards may be provided and maintained.

After the two papers, Prof. J. Rotblat (St. Bartholomew's Hospital Medical College, London) opened a lively discussion on the method described by Mr. Hawkings of evaluating the correction for absorption in the source mount and on the effects of backscatter on the correction. There was some discussion also on the relative accuracy of the various counting methods; Mr. Hawkings considered that a great drawback of the coincidence method is the complexity of the electronic apparatus, which permits errors to arise.

Dr. Robinson was also in the chair for the first session on the following morning, when the subject was "Temperature". Dr. H. van Dijk (Kamerlingh Onnes Laboratory, University of Leyden) read a paper on "The Extension of the International Temperature Scale below the Oxygen Point", in which he summarized and discussed the most recent measurements of the thermodynamic temperature of the boiling point of hydrogen and helium, with the possibilities for interpolation between these fixed points and for extension of the scale below 4·2° K.

This was followed by a paper by Mr. C. R. Barber (National Physical Laboratory) on "Improvements in the Realization of the International Temperature Scale over the range –182·97° C. to 630·5° C.", an account of work in progress at the National Physical Laboratory. A platinum resistance thermometer and Smith bridge of new design were described; the noteworthy feature of the bridge is the form of the coils, which are specially wound to give freedom from mechanical strain. An account was also given of apparatus of new design for realizing the steam and sulphur points.

Dr. L. A. Sayce, superintendent of the Light Division, National Physical Laboratory, was chairman for the next session, which dealt with "The Standard of Luminance", and Dr. J. W. T. Walsh (National Physical Laboratory) presented the first paper, on "The Establishment of the Photometric Scale at the National Physical Laboratory", in which he described the primary standard of light, the preparation of sub-standards and working standards and the accuracy which can be assigned to the results of measurements made at the Laboratory on lamps submitted for standardization. M. J. Terrien (Bureau International des Poids et Mesures, Sèvres) then read a paper on "Co-ordination of the Photometric Units at the B.I.P.M.", in which he described the arrangements made for comparing the photometric units of the standardizing laboratories of France, Great Britain, United States, U.S.S.R., Germany and Japan, and the equipment of the photometric laboratory at Sèvres. It is estimated that the precision with which the B.I.P.M. comparisons indicates the value of the photometric standards throughout the world is, on an average, three or four parts in a thousand; an important source of error is variation in the lamps during transport.

For the final session, on "Standards of Frequency", the chair was taken by Mr. R. S. J. Spilsbury, superintendent of the Electricity Division, National Physical Laboratory. Dr. Erik Bergstrand (Kartverket, Stockholm) read a paper on "The Precision of Optical Methods for the Determination of the Velocity of Light", in which he made a critical survey of the methods and results of the main optical experiments and described in detail his own method in 1950 using a Kerr cell. He believes that the new value first obtained at the National Physical Laboratory by the cavity resonator method is not incompatible with the earlier results when these are given more realistic limits of error; the reason for earlier workers' almost universal arrival at lower values is perhaps that they were unconsciously influenced by the results of the elaborate experiments in 1931 and 1932 with the mile-long evacuated pipe. Dr. L. Essen (National Physical Laboratory) then described, in a paper on "The Measurement of Time, Frequency and Velocity", the recent improvements in the technique of frequency measurement, particularly at microwave frequencies. The measurement of velocity was one application of these techniques and another was likely to be the development of an atomic frequency standard. In the discussion which followed, Mr. J. H. Briggs (Telecommunications Research Establishment), Mr. H. M. Smith (Royal Observatory) and Mr. H. B. Law (Post Office Research Station) all supported the need for an atomic clock, but Dr. L. Hartshorn (National Physical Laboratory) raised the question why we believe that atomic standards will be more nearly constant than other material standards. The question can only be answered by the agreement between different experiments and, as Dr. Bullard pointed out, agreement does not always indicate that the answer is correct.

The full proceedings of the symposium are to be published by H.M. Stationery Office in the course of the next few months. M. M. POSTGATE

OLD MOUNTAINS OF NEW GUINEA*

By L. EVELYN CHEESMAN

FOR all taxonomists interested in the west Pacific the fact that New Guinea possesses series of pre-Cambrian rock that have never been submerged has significance which cannot be over-stressed. Their existence indicates a solution of what otherwise would be inexplicable, namely, whence New Guinea derived its Oriental insect fauna and flora.

The huge island was raised from a drowned land-mass by the Miocene–Pliocene tectonic movements. So much is well known; but this furnishes no working hypothesis for botanists or for entomologists. The deductions which appear self-evident actually conflict with biological data; and, owing to their antiquity, it is to the insects and plants that we must turn for convincing evidence of land movements.

Land raised from the ocean bed during the Tertiary, its only subsequent continental connexion being periodically with Queensland and by sundry land bridges to Asia through the Philippines, might be expected to possess a flora and fauna basically Australian with an Oriental influence. Moreover, they should be discontinuous with many lacunæ in their totality. On the contrary, analyses of species belonging to any important group reveal an undoubted Oriental origin. There is an Australian element—more or less strong according to the group. There is a Malaysian influence attributable to a common Asiatic ancestry. There is a very rich peculiar neo-endemism suggesting isolation over a long period which makes Papuasia, that is, New Guinea with adjacent islands and archipelagoes, an extremely distinct zoological sub-region in geologically recent times. The flora and insect fauna are harmonious, their totalities show no serious lacunæ and no important group is unrepresented.

Papuasia therefore ranks with Australia and Asia in its continental full populations and not with neighbouring land-masses, Sumatra, Java and Borneo. These were also raised during the Tertiary, connected for a period with Asia and then isolated; but they possess a discontinuous flora and insect fauna.

Whence then did New Guinea receive its continental populations, since palæogeology apparently does not support the conclusions of botanists and entomologists?

We find on analysis of species that: (1) the average ratio of the older species groups is one-tenth Australian, three-tenths Asiatic, and six-tenths endemic; (2) the nearest genera allied to Papuasian endemic genera are found in Asia; (3) genera which are represented in both Malaysia and Papuasia are also found in India, Burma or China, often in all three countries. This points to a two-branched migration from the continent, which can be foreseen because there has been no land connexion between Malaysia and New Guinea subsequent to the Late Cretaceous. Otherwise the Sumatra tiger and monkeys and apes would have found their way to the New Guinea forests.

Before the War, Prof. Lam, of Leyden, was engaged on an analysis of the flora of Malaysia and Dutch New Guinea. He found that the proportionate representation was approximately the same as in the Insecta, and he agreed also with points (1), (2) and (3). Botanists have a decided advantage over entomologists in such matters because their material collected and determined is far more abundant. As in the Insecta there are no very old forms; the slight South American influence comes through Australia. There are many endemic genera but no endemic family.

The fact that there are two distinct geanticlines in New Guinea belonging to different periods sheds a most important light upon these questions of the distribution of species. The ancient geanticline was investigated by the Australian government geologist, R. C. Stanley, and his results were published in 1923. He directed attention to the existence of this ancient wrecked mountain system represented by relics, some of which have never been submerged, pre-Cambrian and Asiatic in origin. They are situated along the northern coast of New Guinea with the same alignment as the young Tertiary central ranges which are Malaysian in origin. It is concluded that as the folding movements raised the central ranges the greater part of this old northern system was submerged. The series comprises south-west New Britain, which is still subsiding and has never been submerged, Finisterre Mountains, Torricelli Range, Omake Massiv (Mount Bougainville), Cyclops Range which has never submerged, Japen Island, and Waigeu Island.

These form the margin of a drowned land which for my present purpose I have named Cyclopea. All these remnants are characterized by a strong tilting on their ocean side so that valley heads and gullies alone remain above the sea, and on their shoreward side there is a proportional elevation with much weathered cliffs of Cretaceous limestone containing Eocene Foraminifera. There has been land subsidence on a huge scale.

If we conceive this lost land-mass Cyclopea as having maintained connexion with Asia until the Early Pliocene, there we have ancient fully populated land from which the young land would be colonized as it rose from the ocean bed. This is acceptable to geologists and accords with the biological evidence. It is, in fact, the only working hypothesis satisfactory for taxonomists. The drift and overthrust of continents in that part of the globe does not directly concern biologists of New Guinea to-day, because Cretaceous New Guinea of yesterday, which with New Zealand formed the margin of Australia, was submerged, and the stupendous folding movements entirely altered all previous land formation.

Cyclopea has a different history; but whether palæogeologists decide that the land looped, festooned, arched, buckled, or streamed by New Guinea with the Solomon Islands in pursuit is immaterial to us. What we do insist is that they must postulate Cyclopea as a continuous land to Asia through the Moluccas and the Philippines prior to the Early Pliocene, otherwise any hypothesis will be rejected as untenable because of the testimony of botanists and entomologists.

Pure *All-trans* Vitamin A Acetate and the Assessment of Vitamin A Potency by Spectrophotometry

The international unit of vitamin A activity corresponds with 0·3 μgm. of vitamin A alcohol or 0·345 μgm. of vitamin A acetate[1]. The International Standard Preparation is a solution of the *all-trans* acetate in cottonseed oil, and it serves a dual purpose as a biological and a spectrophotometric standard of reference. The properties of the acetate are therefore important.

The absorption spectra of many organic solutes vary to some extent in different solvents, even when there is no evidence of equilibria between isomeric forms. In the case of vitamin A such variations have been known to occur since 1935[2]; but they are second-order effects which have hitherto been largely ignored.

Advances in spectrophotometric technique, together with the advent of pure vitamin A and its esters, have made it possible to ascertain the solvent effects with considerable precision, and it is no longer appropriate to neglect them. Further, the spectrum of vitamin A alcohol (expressed in terms of molar extinction coefficient plotted against wave-length) is not necessarily identical with that shown by its esters in the same solvent. Granted that solvent effects occur, it is necessary to establish their magnitude in relation to the degree of accuracy which is both attainable and worth while. The present report is the result of work in five laboratories on synthetic samples (supplied by Dr. O. Isler of Hoffmann-La Roche, Basle). We are satisfied, however, that purified samples of *all-trans* vitamin A acetate obtained from natural products (and supplied by Dr. J. Matet of Alimentation Equilibree, Commentry) are identical with the synthetic acetate by chemical and physical tests[3,4].

Properties of *All-trans* Vitamin A
(Each figure is the mean of the results from the five laboratories)

Solvent	Alcohol $\lambda_{max.}$ (mμ)	 ($\epsilon_{max.}$)	Acetate $\lambda_{max.}$ (mμ)	 ($\epsilon_{max.}$)
*Iso*propanol	324–326	52,300*	324–326	50,280†
Ethanol	324–325	52,480*	325–326	51,180
*Cyclo*hexane	320–327	49,760†	327–328	50,000†
Light petroleum (40°–60°)	324–326	52,000*	324–326	52,200*

Analysis of variance of the forty individual results indicates that: (1) the coefficient of variation between laboratories is 1·3; (2) the residual coefficient of variation of the one determination is 1·1; (3) the four means marked * are not significantly different; (4) the three means marked † are not significantly different; and (5) the remaining mean (51,180) falls between the other two groups and cannot confidently be regarded as a normal sampling variant of either. The two coefficients of variation given in (1) and (2) are normal—perhaps, indeed, rather below (that is, better than) normal. With the possible exception of the *cyclo*hexane result, the given mean values are generally consistent with those in the literature. Most published figures, however, favour a 1–2 per cent lower value for vitamin A esters in *cyclo*hexane than in *iso*propanol.

It follows from the above, and from the definition[1] of the International Unit of vitamin A so as to give a potency of $3\cdot\dot{3} \times 10^6$ I.U./gm. to the *alcohol*, that the appropriate factors for conversion of values at $\lambda_{max.}$ to I.U. per gram are most likely to be those given below:

Conversion Factors

Solvent	Vitamin A alcohol	Vitamin A acetate
*Iso*propanol	1,825	1,906
Ethanol	1,825	1,850
*Cyclo*hexane	1,906	
Light petroleum (40°–60°)	1,825	

The value of 1,906 for vitamin A acetate in *iso*propanol corresponds to an E(1 per cent, 1 cm.) value of 1,525, identical with the figure accepted by the Expert Committee on Biological Standardization of the World Health Organization[1]; and that body recommended the rounded-off factor 1,900 for practical purposes.

Now, in practice, vitamin A is often estimated in the form of the alcohol (the U.S. Pharmacopœia assay[5] stipulates saponification of vitamin A-containing oils, and chromatographic methods may involve saponification) for which the factor 1,900 would seem to be about 4 per cent too high if the final solvent is *iso*propanol. *Cyclo*hexane, on the other hand, would take the 1,900 factor under all conditions. In light petroleum $\epsilon_{max.}$ is apparently identical with $\epsilon_{max.}$ in *iso*propanol for the alcoholic form of the vitamin. This has certain practical advantages.

It should be emphasized that use of the conversion factors here accorded would not cut across the recommendation of the World Health Organization Committee, because the primary definition of the International Unit of activity is a weight of the vitamin, and the conversion factor is derivative. The presence of some neo-vitamin A (an isomer) in natural products is an additional complication. This point has been discussed by several authors[4,6] and will not be considered here.

Simple Equipment to Estimate Radiocarbon

We have built a low-pressure argon-alcohol counting tube of very satisfactory performance for radioactive carbon dioxide (Fig. 1). The cathode is a brass cylinder of 16 mm. diameter, 0·5 mm. thickness and 80 mm. length. A wire is soldered to the cylinder and sealed into the glass with a thermosetting plastic ('Araldit', Ciba). The anode, tungsten wire of 60 μ, is kept taut by a steel spring, and again sealed in with 'Araldit'. 'Pyrex' is used.

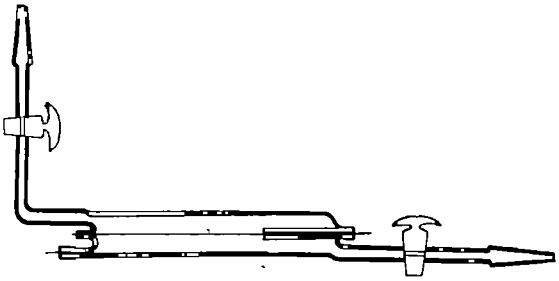

Fig. 1

The active carbon dioxide is generated in an all-glass vacuum line (Fig. 2) from barium carbonate and perchloric acid. The gas is dried by silica gel, and the carbon dioxide frozen out in a U-shaped capillary with liquid air. (No carbon dioxide is found to be held back by the silica gel.) After freezing the carbon dioxide, taps *A* and *B* are closed. Alcohol vapour is introduced into the filling line and the attached counting tube to a pressure of 15 mm. mercury. Now the liquid air is removed and tap *B* is opened again, until the desired pressure of carbon dioxide is attained. Finally, 3 cm. pressure argon is let in, and the counting tube is shut.

The length of the plateau is 250 volts with a gradient of 1–2 per cent/100 volts up to a carbon dioxide pressure of 5 cm. (Higher pressures could not be tested for want of a source of sufficiently high voltage; at carbon dioxide pressures of 1, 3, 5 cm. the plateau voltages were 1,150, 1,450, 1,800 volts.) The background of the counter, under 3 cm. of lead, is 28 min.$^{-1}$; it does not increase with time, that is, no radiocarbon is held back by the counter. Extreme differences in measured activities between repeated fillings, supposed to be identical, are 3 per cent. This reproducibility is at present limited only by the precision of the mercury manometer. The measured activity is strictly proportional to carbon dioxide pressure. The total time required to generate carbon dioxide and fill the counter is about two hours.

Loss of activity in air (through exchange) on heating barium carbonate, prepared as described below, for one hour, was found to be zero at 100°, 5 per cent at 300°, 11 per cent at 500°, and 15 per cent at 700° C. The rate of loss rapidly decreases with time: at 400° C., the losses after 1, 2, 4, 8 hr. were 8, 10, 11, 12 per cent respectively. In view of the fairly small losses at elevated temperatures, losses at room temperature are curiously high 7, 9·5, 16 per cent after 7, 10, 18 days. Apparently a different mechanism operates at low temperature. At 100 per cent relative humidity, the losses at room temperature even reach values as high as 9·5, 16, 17, 17·5 per cent after 2, 6, 9, 11 days. Marked loss (3 per cent) has also been observed, after one hour, on stirring freshly precipitated barium carbonate with water.

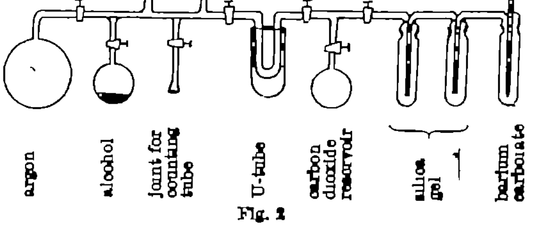

Fig. 2

It follows that no loss need be feared if samples are handled reasonably quickly in air; but kept in an atmosphere free from carbon dioxide for longer periods. In fact, no specific activity was lost at all in a cycle involving generation of carbon dioxide from barium carbonate, absorption in caustic potash, reprecipitation as barium carbonate—after addition of ammonium chloride to reduce alkalinity—with barium chloride, and drying in an oven in air at 140° C. for half an hour.

We thank Prof. K. Przibram and Prof. L. Ebert for their constant support, Dr. W. J. Arrol for the gift of radiocarbon, and our colleague Mr. H. Ebenberger for much friendly help.

A New Radio Method for Measuring the Electron Density in the Solar Corona

Present estimates of the electron density in the solar corona are based on the measurements during an eclipse of the optical radiation which originates in the photosphere and is scattered in the corona[1]. These measurements and their interpretation present considerable difficulties, particularly when attempts are made to determine the electron density in the outermost layers of the corona[2,3]. In this communication a possible method of determining the electron density at different heights in the corona is suggested, which should allow the exploration of regions where the density is as low as 10^4 cm.$^{-3}$.

It can be shown that if the radiation from a remote source passes near a spherical transparent body in which the refractive index increases outwards, and the angular separation between the source and the centre of the sphere is less than a certain value, no radiation from the source can reach the observer. At larger separations, a deviation of its apparent position occurs. If, therefore, a radio star is situated in a direction near that of the sun, the radiation on certain frequencies may be 'occulted' even when the radio star is at a considerable angular distance from the visible limb. Using the existing data on coronal electron density, it can be shown that, for frequencies of 210, 81·5 and 38 Mc./s., the effective radii of the sun for occultation are of the order of $2 \cdot 9 R_{\odot}$, $3 \cdot 6 R_{\odot}$ and $4 \cdot 5 R_{\odot}$ respectively, where $R_{\odot}$ is the photospheric radius. A precise determination of the values of the radii for a number of frequencies would allow the distribution of electron density with height to be deduced.

In order to perform this experiment, it would be necessary to observe the radio star when its direction is very near that of the sun; the solar radiation is then likely to mask the much weaker radiation from the star. It is, however, possible to reduce the effect of solar radiation, without reducing that from the star, by using an aerial arrangement which is relatively insensitive to sources subtending a comparatively large angle. It has been shown[4,5] that if an interferometer aerial were used with an aperture of 100–200 wave-lengths, the response from the sun would be reduced by about 98 per cent, although the response from a radio star would not be reduced at all. The presence of intense radiation from sunspots cannot unfortunately be eliminated so simply, owing to the smaller angular diameter of the sources of radiation; very much greater resolving powers would therefore be necessary.

It was noted that the intense radio star 05·01 in Taurus (R.A. 05^h 31^m 34^s, decl. 22° 04′)[6] offered the possibility of carrying out this experiment, since with the existing aerial systems its intensity was sufficient to allow observations even in the presence of weak sunspots. A series of observations was carried out during June 1950 when the direction of the sun passed near the radio star (the minimum separation was about $4\ R_{\odot}$) and again in the corresponding period in 1951. During the latter observations, interferometers of aperture 205, 105 and 60 λ were used on frequencies of 210, 81·5 and 38 Mc./s. respectively.

Unfortunately, during both these experiments, sunspot radiation was abnormally intense, and no useful results were obtained. It is hoped to repeat the experiment in the future, when the sunspot activity is likely to decrease, possibly using aerials of greater resolving power. The co-ordinates of the radio star may then also be known with greater precision. The use of aerials of increased resolving power might also make it possible to use other less intense radio stars, and so increase the number of occasions on which the experiment could be carried out.

This work was carried out as part of a programme of radio research at the Cavendish Laboratory, supported by the Department of Scientific and Industrial Research, to which also one of us (K. E. M.) is indebted for a senior award. We are grateful to Mr. M. Ryle for suggesting the method.

Structure of Amorphous Aluminium Oxide Films

ALUMINIUM generally is covered with an oxide layer which gives excellent protection against corrosion. Preston and Bircumshaw[1] and other workers, using the electron diffraction method, showed that the layers are not crystalline. Their electron diffraction photographs show two diffuse rings which have not yet been explained satisfactorily. In air and at temperatures below the transition into the crystalline phase, the oxide layer grows very slowly, and only up to about 100 A. in thickness. Consequently, as the layer is too thin for X-ray methods, electron diffraction techniques have to be used.

Diffuse electron diffraction rings can be interpreted in two different ways. Commonly they are explained by a size effect only. It is assumed that the material consists of normal crystals the grain size of which is exceedingly fine. Using this method, Belwe[2] evaluated the size of the individual crystals to be equal to about one elementary cell of γ-Al_2O_3. Belwe thinks that the diffuse rings found are due to the (220) and (440) reflexions, and the assumption is made that (220) and (440) are the strongest reflexions of Al_2O_3; other investigators, however, found (311) to be the strongest pattern.

The second possibility is to assume that the layer consists of totally disordered uniformly built molecular groups. It is then necessary to find, by trial and error, a molecular group such that the electron diffraction patterns which are calculated by the formula derived by Debye[3] and Ehrenfest[4] for the molecules of a gas:

$$I = \text{const.} \sum_i \sum_j \Phi_i \Phi_j \frac{\sin x}{x},$$

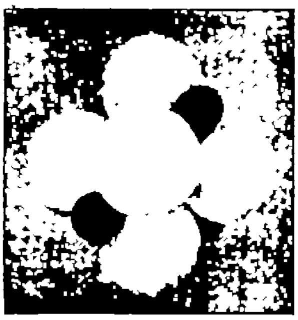
agree with the experiment. In that formula, I is the intensity, $\Phi = \dfrac{Z - F}{\sin^2 \theta/\lambda^2}$ is the atomic scattering factor for electrons, Z is the atomic number, F is the atomic scattering factor for X-rays, θ is the glancing angle, λ the wave-length and $x = 4\pi \,.\, l_{ij} \dfrac{\sin \theta}{\lambda}$, with l_{ij} the distance between the atoms i and j in the particle. Debye[3] further derived a correction for X-ray diffraction in gases and amorphous substances which takes account of the mutual distances between all the atomic groups. He found this correction to be appreciable in the case of a substance of bi-atomic molecules. That correction should be considered whenever the above method is used. The first investigations using this second method were carried out by König[5]. For amorphous germanium König found that its diffraction patterns show that it consists of tetrahedral particles, a result which has been confirmed recently by X-ray diffraction methods.

In the present investigation, I have investigated amorphous aluminium oxide (Al_2O_3) by the same method. The oxide films were grown in air (400° C., 75 hr.). They were lifted free by a dilute mercuric chloride solution, washed and placed on specimen carriers with holes of 0·08 mm. diameter. The films were investigated with 40–60 kV. electrons in transmission. The photographs obtained were measured with a photometer, and the corresponding intensity curves were plotted. The maxima lay at $\sin \theta/\lambda = 0{\cdot}17$ and at $0{\cdot}36$.

After a number of unsuccessful attempts to find the atomic arrangements of the groups, a particle consisting of two Al_2O_3 molecules was found to give a good result (see photograph). This particle is an octahedron of six closely packed oxygen ions with four aluminium ions in a tetrahedral arrangement. The ionic distances involved correspond to those of the γ-Al_2O_3 lattice. They are:

O – O = 2·80 A.
O – O = 3·95 A.
O – Al = 1·73 A.
O – Al = 3·28 A.
Al – Al = 2·80 A.

The Debye correction[3] for the present case is negligible; but the intensity due to the inelastic



Model of the particle found, consisting of two Al_2O_3 molecules

scattering was taken into consideration, for which purpose the table of Bewilogua[7] was used. It should be stressed that the exact atomic arrangement of the particle found does not occur in the γ-Al_2O_3 lattice.

A detailed account of the present investigation and a discussion of the mechanism of the oxidation process will be published shortly. The present communication is published by permission of the South African Council for Scientific and Industrial Research.

Estimation of the Approximate Ionization Constants of Inorganic Bases

Most of the common acidic compounds can be classed as derivatives of the hydrides:

$$H_3O^+ \rightarrow H_2O + H^+ \quad \Delta G^\circ = -\ 1 \text{ kgm.cal.}$$

$$H_4N^+ \rightarrow H_3N + H^+ \quad \Delta G^\circ = +\ 13 \text{ kgm.cal.}$$

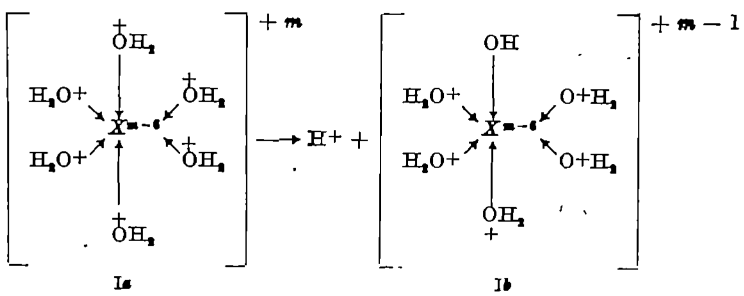
$$H_2O \rightarrow HO^- + H^+ \quad \Delta G^\circ = +\ 20 \text{ kgm.cal.}$$

Within any of these classes, large differences in the free energies of ionization ($\Delta G^\circ = -RT \log_e K$ for the reaction $BH \rightarrow B^- + H^+$ in dilute aqueous solution at 25° C.) can usually be attributed[1,2] to the presence of charges in the near neighbourhood of the dissociating proton. Each charge on the atom next to the one bearing the dissociating proton will decrease the value of ΔG° by about 14 kgm.cal. if positive and will increase ΔG° by about 14 kgm.cal. if negative. The effect of a charge upon ΔG° is reduced when it is situated farther from the dissociating proton and $\pm 14Q/2^n$ kgm.cal. has to be added to ΔG° to account for the effect of a charge, where n is the number of atoms between the atom bearing the charge and the dissociating proton[2,3].

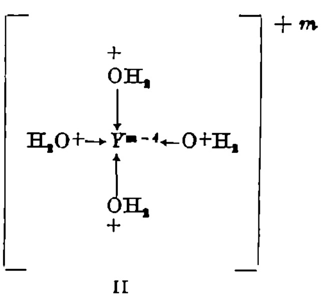
The ions of many inorganic bases are hydrated and may be regarded as acids[1,4]. For example, in aqueous solutions, and in many crystals as well, simple chromic salts contain the hydrated ion[5] $[Cr(H_2O)_6]^{3+}$. Brönsted and Volquartz[4] have shown that this ion is a moderately strong acid and they give a value of $\Delta G^\circ = 5 \cdot 1$ (at 15° C.) for its ionization. This chromic ion (Ia, X = Cr, m = 3) is a derivative of H_3O^+. There are three negative charges on the chromium atom, to which are attached five positive oxygen atoms besides the oxygen atom bearing the dissociating proton. When allowance is made for these charges, a value of $\Delta G^\circ = -1 + (3 \times 14) - (5 \times 7) = 6$ is obtained. A correction should be made to this calculated figure for symmetry factors, since there are twelve equivalent protons in the acid (Ia) and only one basic position in the base (Ib); $RT \log_e 12/1 = 1 \cdot 5$ should be subtracted from the figure calculated above, bringing ΔG° to 4·5 kgm.cal., which is close to the observed value. It would be expected that any hydrated trivalent ion of formula (I) would have a ΔG° value in the neighbourhood of this calculated figure. Brönsted and Volquartz[4] measured the ionization constants of the trivalent ions of iron and aluminium, and their experimental figures give ΔG° equal to 2·9 and 6·5 respectively. In more recent determinations, ΔG° values for the ferric ion (4·0[6]; 3·5[7] and 3·2[8]) closer to the calculated figure have been obtained.

These values approximate to the calculated value, and it should be borne in mind that it is difficult to ensure that the experimental ΔG° value is a true measure of the free energy of ionization of one hydrated ion. The degree of hydration of the ion may change on ionization. Some metallic complexes condense to form ions containing more than one atom of the metal, while the measurements have to be carried out in the presence of several species of ions, and many ions, for example, chloride and sulphate, readily form complexes with certain metals. Brönsted and Volquartz[4] also measured the ionization constants of cobaltic ions in which some of the co-ordinated water was replaced by ammonia. The ammonium ion is so much less acidic than the H_3O^+ ion that only the hydrogen attached to the co-ordinated water molecules need be considered as dissociating. The calculated and observed values of ΔG° are as follows:

Ion	ΔG° kgm.cal. Found	Calculated
$[Co.4H_2O.2NH_3]^{3+}$	4·5	4·8
$[Co.3H_2O.3NH_3]^{3+}$	6·2	5·0
$[Co.2H_2O.4NH_3]^{3+}$	6·9	5·2
$[Co.\ H_2O.5NH_3]^{3+}$	7·5	5·6



Ia Ib



II

The substitution of a divalent atom ($m = 2$) for a trivalent atom ($m = 3$) in (I) will increase ΔG° by 14–18·5 kgm.cal., in good agreement with ΔG° values of 17·3 and 18·2 found for the ionization of the hydrated calcium ion and barium ion respectively. These ΔG° values are calculated from the second basic dissociation constant of calcium hydroxide[9,10] and of barium hydroxide[10,11], which seem to be known with fair accuracy because recent determinations by different methods have given results in excellent agreement. The second basic dissociation constant for magnesium hydroxide gives ΔG° equal to 15·5 for the ionization of the hydrated magnesium ion[12], which is decidedly lower than the value of 18·5 just calculated for the hexahydrate (I, X = Mg, $m = 2$). In these calculations of ΔG° no allowance has been made for steric effects or for differences in the electronegativities of the atoms in the complexes. Some increase in the acidity of the magnesium ion might be due to steric effects in the hexahydrate of this small ion and to the fact that magnesium is more electronegative than calcium and barium[13].

All the ions mentioned above have been taken to be hexahydrates, as would be expected[14]. When the degree of hydration of a metallic ion is known, a rough estimate can now be made of its ΔG° value for ionization. Thus any monovalent ion X (I, $m = 1$) would be expected to give a value not very far from 32·5 kgm.cal. Alternatively, if ΔG° has been determined, it may be possible to suggest the degree of hydration. Thus, for the ion (II) with m equal to 1, the calculation of ΔG° gives $-1 + (3 \times 14) - (3 \times 7) - 1{\cdot}2 = 18{\cdot}8$, which is close to the value of 18·5 recently obtained[10] for the thallous ion.

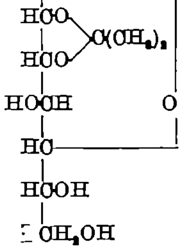
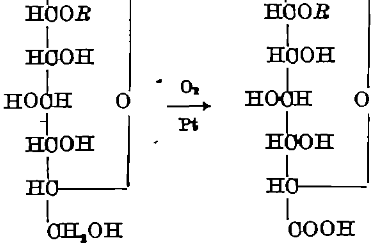
Catalytic Oxidation of Glucosides to Glucuronides

STUDIES of the structure and metabolism of the conjugated glucuronides formed from alcohols and phenols in the animal body have been hindered by the lack of a convenient method for the synthesis of these compounds. Controlled oxidation of the corresponding glucoside would appear to hold most promise as a method of glucuronide synthesis. This oxidation has been carried out with α-menthol and α- and β-methyl glucosides[1–4]. The reagents so far employed (bromine, hydrogen peroxide and nitrogen tetroxide) have, however, given very poor yields of the glucuronides.

Fernandez-Garcia *et al.*[5] have recently found that 1,2-*iso*propylidene glucose (I) is smoothly converted to the corresponding derivative of glucuronic acid when oxygen is passed through the solution in the presence of a platinum catalyst. Comparison of (I) with the general formula for an α-glucoside (II) suggested that this procedure might be employed to oxidize the latter to the α-glucuronide (III). As described below, *l*-menthol α-D-glucuronide (III, R = menthol) was obtained in good yield by catalytic oxidation of the glucoside (II, R = menthol), and the technique was found to be equally applicable to the preparation of *l*-menthol β-D-glucuronide. The possibility of preparing galacturonides and mannuronides by this method is at present under investigation.



(I)



(II) (III)

l-Menthol α-D-glucuronide. 500 mgm. *l*-menthol α-D-glucoside and 100 mgm. platinum black were suspended in 80 ml. water and maintained at 65°. Oxygen was passed through the liquid, which was stirred and kept neutral to litmus by addition of dilute sodium bicarbonate solution. After 10 hr., one equivalent of alkali was consumed and no further change in pH occurred. All the glucoside had gone into solution at this stage. The catalyst was removed by filtration and the solution evaporated to a small volume. On acidifying to congo red with hydrochloric acid, the crude glucuronide, melting point 135–36°, separated in 31 per cent yield. Recrystallization from a mixture of ethyl acetate and petrol ether, boiling point 100–20°, gave a pure product which was identical with an authentic specimen prepared by the method of Bergmann and Wolff[1] (see table).

	Product from catalytic oxidation	Reference compound	Mixture
l-Menthol α-D-Glucuronide (hydrated)	m.p. 141–42° $[\alpha]^{21^\circ}_D = +45{\cdot}6^\circ$	m.p. 137–38° $[\alpha]^{21^\circ}_D = +45{\cdot}9^\circ$	m.p. 141°
l-Menthol β-D-Glucuronide (hydrated)	m.p. 75–77° $[\alpha]^{21^\circ}_D = -99{\cdot}3^\circ$	m.p. 79–80° $[\alpha]^{21^\circ}_D = -101{\cdot}7^\circ$	m.p. 78–80°

Melting points are uncorrected.

l-Menthol β-D-glucuronide. 100 mgm. platinum black was added to a solution of 500 mgm. *l*-menthol β-D-glucoside monohydrate in 50 ml. water and the oxidation was carried out as described above. The reaction was complete in 4 hr. After removing the catalyst, the glucuronide was precipitated as the ammonium salt and then converted to the free acid[6]. One recrystallization from water gave the impure glucuronide, melting point 65–75°, in 34 per cent yield. A further recrystallization gave the pure glucuronide, which proved to be identical with a specimen of biosynthetic *l*-menthol glucuronide[6] (see table).

I wish to express my gratitude to Dr. G. A. Levvy for encouragement and advice in this work.

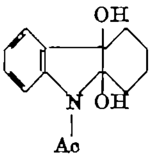
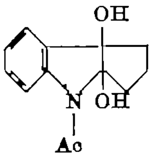
Perhydroxylation of Indole Derivatives by Osmium Tetroxide

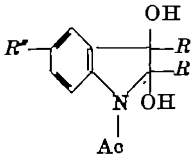
The very various transformations undergone by 9-acetyl-10 : 11-dihydroxyhexahydrocarbazole (I) have recently aroused some interest[1]. The related compound (II) does not undergo Wagner–Meerwein rearrangements like those given by (I)[2]. Witkop[1a] has satisfactorily explained this failure by pointing out that such rearrangement of (II) would involve the formation of a four-membered ring compound. While this suggestion is convincing, it seemed worth while to confirm that the diols (I) and (II) possess similar configurations, for the Wagner–Meerwein change is markedly affected by the *cis*- or *trans*-configuration of the compound involved, only the *cis*-diols becoming readily rearranged[3]. Further, (I) and (II) have hitherto been prepared by rather different methods.



I



II



III

Most of the small number of known diols of type (III) have been obtained by Perkin, Plant and their associates[4], by the action of nitric acid in acetic acid upon the acylated indoles. We have now prepared such compounds by treating various N-acetylindoles with osmium tetroxide and pyridine in benzene solution, and afterwards hydrolysing the highly crystalline, fawn-coloured esters which were formed. Thus, N-acetyltetrahydrocarbazole gave (I) (found: C, 68·3; H, 7·1; calc. for $C_{14}H_{17}O_3N$: C, 68·0; H, 6·9 per cent), melting point 203–204° alone and mixed with an authentic specimen; and (II) (found: C, 66·7; H, 6·6; calc. for $C_{13}H_{15}O_3N$: C, 66·9; H, 6·5 per cent), melting point 149–151°, identical with the preparation of Plant and Tomlinson[2], was obtained similarly.

Other examples, obtained from the appropriate indoles, which might be mentioned, are (III; $R = R' =$ Ph; $R'' =$ H), melting point 206–208° (found: C, 76·8; H, 5·6; $C_{22}H_{19}O_3N$ requires C, 76·5; H, 5·5 per cent), and (III; $R = R' = R'' =$ Me), melting point 102–108° (found: C, 66·3; H, 7·4; $C_{13}H_{17}O_3N$ requires C, 66·3; H, 7·3 per cent). Likewise, N-acetyl-2 : 3-dimethylindole gave a product of melting point 130–133° (Plant and Whitaker[5] give melting point 132–134° for (III; $R = R' =$ Me; $R'' =$ H)).

The method of preparation of these compounds proves conclusively that they possess the *cis*-configuration[6].

A more detailed and extended description of these and other experiments in perhydroxylation of indoles will be given later. We are greatly indebted to Dr. Plant and Dr. Tomlinson, who kindly provided specimens of their preparations of (I) and (II).

Estimation of Deoxycorticosterone by a Modified Hagedorn–Jensen Procedure

Heard, Sobel and Venning[1] demonstrated that estimation of the reducing powers of lipid-soluble extracts prepared from urine provides a measure of the corticosteroid content of such extracts. The value of the method depends upon the presence of characteristic reducing groups in the corticosteroid molecules, making it possible to utilize oxidation reactions similar to those used in the estimation of sugars. Various methods based on this principle have been reviewed by Sprechler[2].

It is of interest in this connexion to report some experimental findings on a convenient and rapid procedure which we have recently developed for the estimation of pure deoxycorticosterone and its acetate in aqueous methyl alcohol solution, based on a modification of the Hagedorn–Jensen blood sugar method[3]. This modification was made possible by employing the reaction which takes place when ammonium molybdate solution is added to potassium ferrocyanide solution in presence of strong acetic acid. The intensity of the brown coloration produced is a direct measure of the amount of ferrocyanide present and may be estimated by a colorimetric or absorptiometric method, thereby avoiding the necessity for the thiosulphate titration.

The standard procedure adopted was as follows: 1 ml. of 50 per cent aqueous methyl alcohol containing deoxycorticosterone or its acetate was measured into a tube, treated with 2 ml. of the Hagedorn–Jensen[3] alkaline ferricyanide reagent, and the tube immersed in a boiling water-bath for 3 min. A blank estimation on 1 ml. of 50 per cent aqueous methyl alcohol was carried out simultaneously. After heating, the tubes were rapidly cooled and the contents made up to 6 ml. with distilled water. 1 ml. of 10 per cent ammonium molybdate solution was added, followed by 5 ml. glacial acetic acid, and, after mixing, the colours (which are stable up to at least 1 hr.) were read on a Spekker photoelectric absorptiometer, using Ilford violet filters.

Representative results showing the effects produced by standard quantities of deoxycorticosterone and its acetate, compared with certain non-reducing steroids, are shown in the accompanying table.

Steroid	Quantity (µgm.)	Extinction
Deoxycorticosterone	50 100 150	0·175 0·344 0·505
Deoxycorticosterone acetate	50 100 150	0·180 0·350 0·510
Androsterone Dehydroisoandrosterone Cholesterol	45 104 250	0·025 0·025 0·025

It will be noted that the reaction distinguishes sharply between deoxycorticosterone or its acetate and the other steroid compounds tested, and that the effects produced by deoxycorticosterone and its acetate are closely comparable. We have found further that the extinction value is proportional to the amount of either up to at least 200 µgm., and that reproducible standard graphs may be obtained over this range with an accuracy ± 5 per cent.

Promising results have also been obtained on application of this method to lipid extracts of urine, and further work on the suitability of the method for the routine estimation of corticosteroids in urine is being carried out in this Department.

We are indebted to Messrs. Organon, Ltd., for supplies of deoxycorticosterone and its acetate.

Separation of Deoxypentose and Pentose Nucleic Acids

CRUDE preparations of deoxypentose nucleic acids are almost invariably contaminated with pentose nucleic acids. This admixture renders many studies of the chemical and biological specificity of nucleic acids difficult. A preliminary separation must be carried out before the exact determination of the constituent purines and pyrimidines becomes possible[1]. Only in a few cases (sperm, thymus and, possibly, spleen) will suitable washing of the biological material, prior to its extraction, sufficiently depress the extent of contamination of the nucleic acid specimens[2-4].

Among the methods for the removal of pentose nucleic acids occasionally found useful in this laboratory, the following may be mentioned. (1) Separation by electrophoresis[5]: this mild, but laborious, procedure has proved particularly suitable for the purification of microbial nucleic acids endowed with transforming activity[6]. (2) Fractionation by way of the calcium salts[5,7]: the separation will, however, be far from complete. (3) Purification of deoxypentose nucleic acids by treatment with crystalline ribonuclease[5,7] and of pentose nucleic acids by the action of crystalline pancreatic deoxyribonuclease[8]: the enzyme-resistant 'cores' are, however, left behind. (4) Dialysis against dilute sodium hydroxide of *p*H 13·5 at 30° for 18 hr.[9]: this treatment injures[10], as it purifies, the deoxypentose nucleic acids, though without noticeable change in composition; the pentose nucleic acids are converted quantitatively to mononucleotides[11].

The new method described here permits the almost complete removal of pentose nucleic acids without appreciable loss of deoxypentose nucleic acids. It is based on the observation that under proper conditions pentose nucleic acid is much more readily adsorbed by activated charcoal than is highly polymerized deoxypentose nucleic acid. This diversity appears to be due to a difference in the molecular weight rather than in the chemical nature of these two nucleic acid types. The dialysable fragments[12] resulting from the depolymerization of deoxypentose nucleic acids by crystalline deoxyribonuclease were, in fact, quantitatively adsorbed by charcoal.

A 0·14 *M* sodium chloride solution proved best as the solvent; the extent of adsorption of pentose nucleic acid from distilled water was too small for practical purposes; with 2 *M* sodium chloride solutions greater losses of deoxypentose nucleic acid were incurred. Washed neutral 'Norit A' (pharmaceutical grade) was used as the adsorbent. 'Darco *G*-60' also could be used, though it was found less adsorptive. As a preliminary step, the adsorbent was washed with running tap water for 18 hr., then once with eight volumes of 2 *M* sodium chloride solution and twice with the same quantity of 0·14 *M* sodium chloride solution. The quantitative procedures for testing the purity of the nucleic acid preparations have been noted previously[13]. It is essential that the nucleic acid solutions be thoroughly freed of protein before being subjected to the treatment.

A typical experiment was carried out with a crude preparation of the sodium salt of highly polymerized deoxyribonucleic acid from pig's liver which was contaminated with 30 per cent of pentose nucleic acid. A viscous solution in 0·14 *M* aqueous sodium chloride containing 0·5–1 mgm. of this product per c.c. was shaken at 2° for one hour with 1/15 to 1/20 volume of wet charcoal. After the complete removal of 'Norit' by centrifugation, no pentose could be detected in the supernatant. The recovery of deoxypentose nucleic acid (containing less than 1 per cent of pentose nucleic acid) was of the order of 94 per cent; the loss was partly attributable to the retention of some liquid by the adsorbent.

The treatment has no depolymerizing effect: the recovered deoxypentose nucleic acid showed no change in viscosity, nor did it exhibit thixotropy[14]. In order to exclude the occurrence of a fractionation in the course of this treatment, a solution in 2 *M* sodium chloride containing 1·75 mgm. of calf thymus deoxyribonucleic acid per c.c. was treated three times with larger quantities of 'Norit' (1/8 volume) until only 27 per cent of the original nucleic acid remained unadsorbed. It cannot be stated whether it is significant that the resulting solution had a specific viscosity 26 per cent higher than that of the original solution after the latter had been diluted to the same nucleic acid content. No indications that a fractionation with respect to chemical composition had taken place were, however, obtained. The analysis of the final product for individual purines and pyrimidines showed the proportions of nitrogenous constituents to be identical with those of the untreated deoxyribonucleic acid[1,2].

Full accounts of the successful application of this procedure to the purification of deoxypentose nucleic acid preparations, especially from micro-organisms and from plants, will be published in due course.

Action of Phytopathogenic Bacteria on Pectate Gel

MANY of the bacteria which cause diseases of plants attack their hosts, in the first instance, by breaking down the pectic substances of the middle lamella. This is particularly true of the soft-rot organisms and of those pathogens causing diseases of the parenchyma.

During the course of study on the bacterial die-back and canker of poplar[1], it has been found that the liquefaction of pectate gel is a sound criterion by which the pectolytic abilities of parasitic organisms may be demonstrated. Previous work[2,3] with pectate gel has been mainly confined to soft-rot organisms. By this present method, it has been possible to extend the use of this medium to other pathogens. This medium has the following advantages: (1) it sets rapidly; (2) the action of the bacteria is amplified by the presence of sodium asparaginate, which most of the organisms can utilize as an extra source of carbon and nitrogen; (3) no adjustment of *p*H is needed, provided that the sodium pectate used is neutral or slightly alkaline.

The medium was prepared as follows: 500 ml. distilled water was put into a one-litre beaker with a mechanical stirrer adjusted so that its speed remained constant during the whole process. It was heated with a bunsen burner, and when the water temperature reached 70° C., 15 ml. bromthymol blue followed by 5 gm. sodium pectate were added and the temperature kept constant for five minutes. When the temperature had dropped to 60° C., 2·5 ml. of 10 per cent calcium chloride in water, 0·5 gm. ammonium dihydrogen phosphate, and 1·0 gm. sodium asparaginate were added in succession. The temperature was kept constant for 10 min. The final *p*H of the mixture was between 7·0 and 7·2 (bluish-green) and no adjustment was therefore needed. The medium was then poured into tubes quickly, and autoclaved momentarily at 15 lb./sq. in. The tubes were placed standing in water at room temperature until the gel set in three to four days. They were then stored in a cool place.

A number of organisms, covering the four genera of bacterial plant pathogens, were inoculated by needle stabs into the medium.

The following species of the genus *Pseudomonas* were used: *Ps. syringae*, *Ps. syringae f. sp. populea*[1], *Ps. mors-prunorum*, *Ps. angulata*, *Ps. tabaci*, *Ps. medicaginis f.sp. phaseolicola* and the saprophyte *Ps. fluorescens liquefaciens*. All except *Ps. fluorescens* produced slight to moderate liquefaction and full thick liquid; the medium became alkaline. *Ps. fluorescens* did not liquefy the medium although it grew readily in it.

Of the genus *Xanthomonas* the following species were used: *X. campestris*, *X. citri*, *X. malvacearum* and *X. begoniae*. The first two organisms produced moderate liquefaction and clear liquid, while the others produced slight thick liquefaction. In all cases the medium remained neutral.

All the species of *Corynebacterium* used, namely, *C. fascians*, *C. tritici*, *C. michiganense* and *C. flaccumfaciens*, produced slight to moderate liquefaction, thick liquid and slight alkalinity.

Different types of action were produced by pathogens belonging to the genus *Bacterium*. In the first type, *B. aroideae*, *B. carotovorum* and *B. phytophthorum* produced moderate liquefaction, semi-transparent liquid and acid. In the second type, *B. salicis* produced less liquefaction, thicker liquid and no change in *p*H. In the third type, *B. tumefaciens* produced slight liquefaction, still thicker liquid and alkalinity. The saprophyte *B. lathyri* did not liquefy pectate gel.

It is suggested that the differences in the extent of liquefaction by the various organisms may be attributed to the nature and amount of pectic enzymes they secrete. Two enzymes may be concerned with the breakdown of the pectic salts present in the medium, namely, pectinase and protopectinase. While soft rot organisms secrete a large amount of both enzymes, saprophytic organisms, on the other hand, may secrete pectinase only. Vascular and hyperplastic organisms secrete very little protopectinase, as they do not depend, in their parasitism, on the breakdown of the middle lamella.

Effect of Vitamin B_{12} on the Synthesis of Protein and Nucleic Acids in the Liver

IT is known that the cytoplasm content of the liver is determined by protein nutrition[1], and recently vitamin B_{12} has been shown to promote amino-acid assimilation[2]. A decrease in liver basophile cells (attributable to ribonucleic acid) is observed in rats deficient in vitamin B_{12} [3]. The vitamin also protects against hepatic damage during carbon tetrachloride intoxication, which causes a considerable reduction in the

EFFECT OF VITAMIN B_{12} ON THE PROTEIN AND NUCLEIC ACID CONTENTS OF THE LIVER

Dietary condition	No. of animals	Liver protein nitrogen	Liver nucleic acid phosphorus		
			Total	Deoxyribo-nucleic acid	Ribonucleic acid
		(mgm. per 100 gm. body-weight)			
Fasted 48 hr.	8	85 ± 1·6	3 88 ± 0·30	0·90 ± 0·08	2·96 ± 0·19
Re-fed adequate 10 per cent casein diet :					
(a) without B_{12}	8	101 ± 2·1	4 14 ± 0 20	0 90 ± 0·04	3·22 ± 0 20
(b) with parenteral B_{12} supplement	8	109 ± 1·9	5·24 ± 0·46	1·16 ± 0·08	4·13 ± 0 18

ribonucleic acid content of the liver[4]. All these findings suggest that vitamin B_{12} may influence protein as well as nucleic acid metabolism in the liver. We have sought direct experimental evidence for this in studies based on the regeneration of the labile liver cytoplasmic proteins in the rat following a brief fast. The results of a typical experiment are presented here.

Adult male albino rats weighing 180–220 gm. (average 200 gm.) were chosen for the experiment. They were kept on a vitamin B_{12}-free ration for four weeks to deplete as much of their tissue reserves of the vitamin as possible. To prevent intestinal biosynthesis of the vitamin, 1 per cent of sulphasuxidine was included in the diet. The diet used during the preparatory period, and also for refeeding after the fast, was the same and had the following composition : casein (prepared from commercial casein and devitaminized by exhaustive extraction with ethyl alcohol) 10, coconut oil 10, cane sugar 10, corn starch 65, salt mixture 4, and sulphasuxidine 1. The experimental animals received adequate amounts of vitamins A and D, and all pure vitamins of the B-complex excepting B_{12}.

The duration of the fast was 48 hr. and the period of refeeding four days. Comparable groups of rats were sacrificed at the end of the fast and after refeeding. During the refeeding period, one group served as a control, and the animals in a parallel group received daily 3 μgm. of vitamin B_{12} (Merck's 'Cobione') each intraperitoneally, the food intake in both the groups being restricted to 12 gm. a rat per diem.

The livers were excised from the animals under amytal anæsthesia after thorough bleeding through the abdominal aorta, immediately weighed and homogenized in ice-cold water in a Waring blendor. Aliquots of the homogenate were used for the various analyses. The true protein nitrogen was estimated after precipitating the proteins with trichloracetic acid (5 per cent). The procedure of Brues *et al.*[5] was adopted for fractionating the deoxyribonucleic and ribonucleic acids, their content being determined by estimating the acid-insoluble, non-lipid phosphorus in the different fractions. The results are given in the accompanying table. The liver constituents are expressed in terms of 100 gm. of the body-weight of the animals just prior to the fast.

It is evident from these results that vitamin B_{12} stimulates both protein and nucleic acid synthesis in the liver. The liver protein nitrogen increment over the fasted level is raised by nearly 50 per cent, and the total nucleic acid content of the liver by about 27 per cent in the group receiving vitamin B_{12} as compared to the control. The increases in the deoxyribonucleic and ribonucleic acid components are of the same order as in the total nucleic acids. The greater regeneration of liver protein in the animals receiving vitamin B_{12} is presumably due to its effect in enhancing amino-acid utilization. The changes in the nucleic acid content of the liver produced by vitamin B_{12} are much more than what would correspond to those in its protein content, and are therefore to be considered a specific effect of the vitamin. The rise in the liver deoxyribonucleic acid content brought about by the vitamin appears particularly noteworthy in view of the fact that it is not affected by fasting and even wide variations in dietary protein content[1b,6]. We believe these results are the first experimental proof of the direct intervention of vitamin B_{12} in mammalian nucleic acid metabolism.

Further studies relating to the effects observed are in progress. A detailed account of the findings will be published at a later date.

We are grateful to Dr. V. Subrahmanyan, director of this Institute, for encouragement and interest in the work.

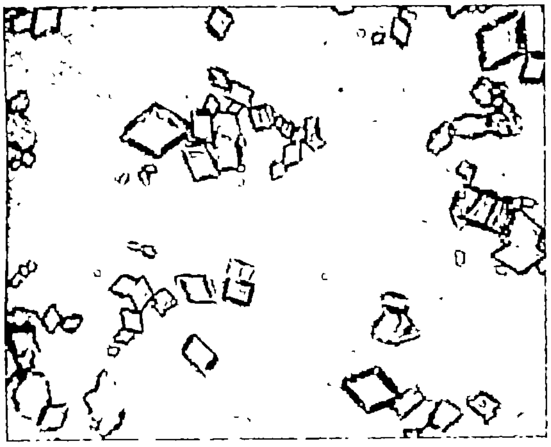
Crystallization of the α-Amylase of *Aspergillus oryzæ*

COMPARISON[1] between crystalline α-amylases of malt[2], bacteria[3], hog pancreas[4], human pancreas[5] and saliva[6] indicate that their properties vary regularly in that order, emphasizing the close relationship which exists between proteins of the same biological activity from the vegetable to the animal kingdom.

As would be expected for a bacterial enzyme, *B. subtilis* α-amylase is much more closely related to the animal than to the vegetable enzymes. For example, as is the case for animal amylases, it is activated by chloride ions. Calcium ions, which are indispensable to malt α-amylase[7], are ineffective.

In order to throw light on variations which occur among the amylases, it appeared of interest to study an enzyme from a material which, from a systematic point of view, would be intermediate between malt and bacterial amylase. With that purpose in mind, we prepared pure amylase of the mould *Aspergillus oryzæ* (taka-diastase).

An aqueous 1 : 6 suspension of 'Clarase 900' (Takamine Laboratory, Clifton, New Jersey, U.S.A.) is left for 12 hr. in the cold. After centrifugation, the dark brown liquor is brought to 0·8 saturation with solid ammonium sulphate. The precipitate obtained by filtration on 'Filter Cel' is dissolved, the solution is adjusted to pH 6·0 and fractionated by acetone. The 40–58 per cent acetone fraction is dissolved in a small amount of water. This solution (pH 7·2) is brought to 0·75 saturation with sodium chloride and then fractionated between 0·54 and 0·70 saturation with a saturated solution of ammonium sulphate. The fractionation is repeated twice under approximately the same conditions. The last precipitate is now dissolved in the minimum quantity of water, and the slightly brown solution, adjusted to pH 7·2, is left in the cold. Crystals appear after two or three days, and, after a week, at least 50 per cent of the activity of the suspension is found in the crystalline material. This has been recrystallized (see photograph).



Crystals of α-amylase from *A oryzae* × 150

A product the activity[4] of which was 2,400 mgm. maltose/mgm. nitrogen has been obtained. The total yield was approximately 15 per cent with a fourfold activity/nitrogen enrichment, based on the original extract. The purified enzyme behaves as a strictly homogeneous substance in the electrophoresis apparatus at all pH's investigated, namely, 4·7–8·6. Its isoelectric point lies at $\sim pH$ 4.

The enzyme is stable in the cold between pH 4·7 and 7·8 and can be dialysed for long periods against aqueous or salt solutions without any loss of activity. Its activity is not dependent upon the presence of chloride ions as for the animal and bacterial amylases, nor does it need calcium ions as does malt α-amylase.

The accompanying table compares some of the properties of taka-amylase with those of other crystalline amylases.

Properties	Crystalline α-amylases of				
	Malt	*Asperg. oryzae*	*B. subtilis*	Pig pancreas	Human pancreas and saliva
Mgm. Maltose/ mgm. N	2,350	2,400	3,600	4,000	6,200
Optimum pH	4·7–5·4	5–7	5·3–6·8	6·9	6·9
Solubility (per cent)	>15	>10	∼5	0·3	0·3
Activation energy (cal./mol.)	7,050	10,500	13,500*	13,500	13,500
Activation by $Ca^{\cdot\cdot}$	+	–	–	–	–
Activation by Cl'	—	—	+	+	+

* At temperatures less than 20° C.

In conclusion, although the properties of crystalline taka-amylase are intermediate between those of malt and bacterial amylase, this enzyme should be considered separately due to the fact that its activity does not depend on the presence of any ion.

We wish to express our thanks to Prof. Kurt H. Meyer for many helpful suggestions and discussions in connexion with this work.

'Streptozyme', a Lytic Enzyme from Lactic Streptococci

IT has already been shown that antibiotic-producing streptococci other than the lactic group (Lancefield's Group *N*) are rare. The difficulties of survey were increased by toxic metabolic by-products, lactic acid in particular giving false inhibitory reactions on agar[1]. During the later stages of this work (unpublished) neutralized culture fluids were used to overcome the inhibitory effects of lactic acid. A cylinder-plate method was used for assays with *Staphylococcus aureus* (491) as the test organism. Several strains of streptococci were isolated from silage, the neutralized culture fluids of which gave 20-mm. zones of inhibition, while the un-neutralized acid culture fluids were inactive. These cultures were proved serologically to belong to Group *N* (*Str. lactis*), yet the inhibitory substance produced is inactive in acid media and is heat-labile, characters distinguishing it from the main antibiotic, nisin, produced by *Str. lactis*[2].

After centrifuging, both cells and supernatant were inactive and the inhibitory substance appeared to be mainly associated with the intact living cells. When growing cells were killed with nisin (200 units/ml.), they promptly became autolysed. Autolysis depended on pH (ceasing completely at pH 6 or below) and on the age of the culture. The activity of cultures more than 10 hr. old declined gradually, even when the pH was maintained by periodic neutralization at 6·5.

The autolytic nature of this enzyme clearly distinguishes it from lysozyme; it also appears to be more heat-labile. The lytic effect is not due to bacteriophage, since a cell-free culture filtrate was incapable of lysing living cells, but there was some activity against a heat-killed suspension. The name 'streptozyme' is proposed for this enzyme.

Deoxyribosenucleic Acid Synthesis during Cell Division in Mouse Epidermis

A STUDY of the energy relations of epidermal mitosis in the adult mouse has shown that active production of energy is of vital importance only during that period which immediately precedes the prophase and for which Bullough[1] has suggested the term 'antephase'. By the time an epidermal mitosis becomes recognizable, it is so highly independent of external conditions that it may be regarded as a classical example of an all-or-none reaction. It appears that the critical importance of the active production of energy in the antephase may be related either to a demand for energy at this time, or to the necessity for energy storage for the maintenance of the cell during some two hours of division and reconstitution[2].

In examining the first of these alternatives it was noted that the view is widely held that an increase in the nucleic acid content of the nucleus occurs during early prophase. Thus Ris[3], using the photometric method of Pollister and Ris[4] for a study of the total nucleic acid content and the deoxyribosenucleic acid content of the cells of onion roots and grasshopper testes, has concluded that "during the mitotic prophase and the first meiotic prophase the constituents of chromosomes increase about twofold". It was suggested by Bullough[2] that this conclusion, if it is also applicable to mouse epidermis, may suggest a reason for the active production of energy in the antephase, since any substantial increase in the nucleic acid content of the cell at this time must involve a significant amount of work.

In contradiction to this, however, Pasteels and Lison[5], using the technique of Lison[6], have shown in the erythrocytes of embryo rats, the crypts of Lieberkühn of adult rats, and chick heart fibroblasts "qu'il n'y a pas de modification de la teneur en D.N.A. au cours de la prophase ; qu'à l'anaphase cette teneur tombe de moitié pour chaque noyaufils ; que la teneur initiale se reconstitue immédiatement au moment de la reconstitution du noyau". Lison and Pasteels[7] have also described a similar pattern of deoxyribosenucleic acid synthesis during mitosis in sea urchin eggs. It was therefore necessary to determine the conditions in mouse epidermis before attempting to relate energy production to deoxyribosenucleic acid synthesis, and measurements have now been carried out on the ear epidermis, the tissue in which the original observations on energy production were made. The mice used were four-month old Kreyberg white label males. These were killed while asleep in order to obtain a high number of epidermal mitoses, their ears were sectioned, and the deoxyribosenucleic acid content of their epidermal nuclei was estimated by the method described by Lison[6] (see table) ; for comparison, the deoxyribosenucleic acid content of lymphocyte nuclei is also shown.

DEOXYRIBOSENUCLEIC ACID CONTENT OF NUCLEI IN THE MALPIGHIAN LAYER OF THE EAR EPIDERMIS OF ADULT MALE MICE (ARBITRARY UNITS)

Type of nucleus	Number of nuclei examined	Deoxyribosenucleic acid content Extreme values	 Mean and standard error
Interphase	150	123–642	—
Prophase	1	362	—
Metaphase	20	333–467	338·7 ± 7·5
Telophase × 2	28	384–568	460·0 ± 10·6
Lymphocyte	26	230–327	276·9 ± 5·3

The measurements showed that in the Malpighian layer, which alone contains cells capable of division, the deoxyribosenucleic acid content of interphase nuclei varied widely. Clearly the Malpighian cells were not homogeneous, and, using lymphocyte values as standard, it was found that they could be roughly divided into three groups : those with a deoxyribosenucleic acid content equal to that of the lymphocytes, those with a lower content, and those with a higher content. It was apparent that only the cells of the last group, those with the highest deoxyribosenucleic acid content, could undergo division, since all the nuclei measured in prophase and metaphase showed similarly high values. During early anaphase each of the two newly forming groups of chromosomes had only half the deoxyribosenucleic acid content of the metaphase nucleus. During late anaphase and telophase, however, deoxyribosenucleic acid synthesis was rapid so that, by the time each daughter cell entered the interphase, it again showed the high level typical of the prophase.

Evidently, conditions in the ear epidermis of the adult male mouse closely resemble those in the crypts of Lieberkühn of the adult rat, concerning which Pasteels and Lison[5] have concluded that "au cours de l'intercinèse, les cellules ont des teneurs très différentes ; en revanche, les valeurs observées à la métaphase sont d'une très grande homogénéité ; la synthèse en D.N.A. débute à l'ana-télophase et se poursuit au cours de la reconstitution du noyau ; la valeur anaphasique est ainsi progressivement doublée ; et une valeur égale à celle de la métaphase est rétablie au début de la nouvelle intercinèse".

These conclusions appear to contradict any suggestion that the high production of energy observed during the antephase may be related to active nucleic acid synthesis at that time, and to be in agreement with the alternative hypothesis that the antephase is the period when energy is stored for the support of all the various cellular activities, including synthesis of deoxyribosenucleic acid, which occur during the ensuing division. A fuller account of these observations will be given elsewhere, together with a description of conditions in the superficial epidermal layers.

A New Biological Method for Evaluating the Efficiency of Insecticides for the Protection of Sheep against Blowfly Strike

THE protection afforded to sheep against blowfl strike by the new synthetic chlorinated hydrocarbo insecticides applied to the fleece has been shown t be the result of two different actions. Insectary test have demonstrated distinct repellent effect and th prevention of oviposition in the case of gravid femal flies, whereas implantations of first instar larvæ, according to the method of McLeod (1937), have indicated the larvicidal role.

The retention of larvicidal properties and the consequent continued protection of sheep long after all demonstrable repellency has disappeared indicate that larvicidal properties are of much greater importance than fly repellence.

It is known that the larvæ of the primary blowfly, *Lucilia cuprina* Wied., live principally upon the serous fluid exuding from the superficial wounds produced by them. In order to determine the minimum concentration of insecticide capable of destroying all first-stage larvæ in a nutritional medium, a series of *in vitro* tests was conducted. First instar larvæ were placed in glass tubes, 3 in. × 1 in., each containing a pledget of cotton-wool soaked in serum in which was suspended the test insecticide in wettable powder form in serial dilutions over the range 1,000–0·004 parts per million. Insecticides in wettable powder form were chosen in order to eliminate the possible larvicidal effect of organic solvents. The tubes were plugged with cotton-wool and held in an incubator at 27° C. (80·5° F.). Observations on mortality were made at 1, 3, 6, 24, 48 and 72 hr. It was unnecessary to extend the observations beyond this period as the maggots become more resistant to insecticidal action with increasing age, and if not killed within 72 hr. will not be affected by the strength of insecticide applied.

Four replications of the above test gave the minimum concentrations of insecticide in parts per million to kill all young *L. cuprina* larvæ in the time specified shown in the accompanying table.

Insecticide	Time (hr.)				
	3	6	24	48	72
Dieldrin	1000	250	16	4	1
Gamma-BHC	250	64	16	4	4
Aldrin	1000	1000	16	16	4
'Methoxychlor'	1000	250	16	16	4
DDT		1000	16	16	4
Chlordane			250	64	16
Toxaphene		1000	250	64	64
DDD (TDE)				64	64

The eight compounds tested fall naturally into four groups according to their larvicidal properties, and both DDT and gamma-BHC are included in the same group as they are capable of killing the larvæ at a dilution of 4 parts per million.

Sheep may be protected for long periods when reated with relatively high concentrations of these synthetic insecticides. Under experimental conditions, DDT at 5 per cent *pp*-isomer affords protection for approximately three months, whereas BHC at 0·5 per cent gamma isomer still protects after six months, provided that at the time of application the wool has a length of 1–1½ in. Under South African conditions, wool grows at the fairly constant rate of ¼ in. per month, so that at the end of three to six months the wool fibres have increased in length by about ¾–1½ in. This new wool, untreated at the time of the original application, was found to be apable of killing first instar larvæ.

In order to ascertain the larvicidal properties of treated wool at various stages after treatment, a group of sheep bearing wool of fibre length 1¼–1¾ in. were treated with the eight different compounds listed in the table in wettable powder form at a concentration of 0·5 per cent of the active ingredients. An area over the rump approximately 12 in. in diameter was thoroughly soaked with each suspension. Commencing nine weeks after treatment, samples of wool of about 0·5 gm. were removed weekly from the treated area on each sheep for laboratory tests, and first instar larvæ were implanted on these areas at the same time.

Half an inch of wool, representing the new growth, was removed from each sample. These portions and the remaining portions of old wool were placed separately in glass specimen tubes and well soaked with normal serum. Into each tube was then implanted 50–100 first instar larvæ of *L. cuprina* for incubation and observation.

The time of survival of the larvæ served as an index of the concentration of insecticide present in the wool samples. By comparing the rates of mortality with those given in the table, an accurate estimation of the concentration of insecticide in the particular portion of the fleeces tested could be obtained.

It was possible to deduce from these *in vitro* tests that the sheep were no longer protected against strike when the concentration of insecticide in the newly grown fleece fell below the larvicidal level, namely, 4 p.p.m. in the case of DDT and BHC. When the larvæ survived in the tubes, strikes developed on the sheep upon which larvæ had been implanted. This method was sufficiently sensitive to indicate partial protection of sheep by observing retarded larval development.

The method described has disclosed distinct differences in the behaviour of the different insecticides in the fleece of sheep. The concentration of gamma-BHC, aldrin, dieldrin, chlordane, and to a lesser extent toxaphene, in the newly grown wool was sufficient to be fully larvicidal nine weeks after application of the insecticide to the sheep which were protected against fresh strike. In the case of DDT, 'Methoxychlor' and DDD(TDE) the larvæ remained alive in the tubes containing the new-growth wool samples, and strikes developed upon the sheep.

The compounds in the first group appear to possess remarkable powers of diffusion down the wool fibres, where they persist at concentrations lethal to first instar larvæ for considerable periods. DDT and its allied compounds, on the other hand, appear to remain fixed in the wool originally treated, and protect sheep for considerably shorter periods in spite of possessing equal larvicidal properties.

Tests conducted to date have revealed that gamma-BHC, aldrin and dieldrin applied originally at 0·5 per cent concentration will diffuse more than 1½ in. along the wool fibre and so provide protection for six months.

The length of wool at the time of treatment and the initial concentration of insecticide applied play an important part in the extent to which diffusion will occur and the degree of protection afforded.

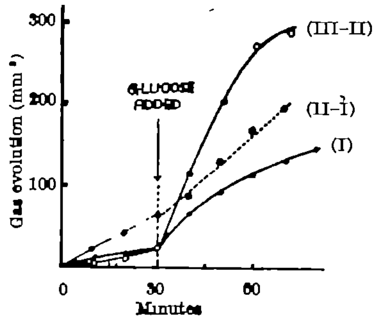
Hydrogen Evolution by *Trichomonas fœtus*

Trichomonas fœtus, a polyflagellated protozoon, is parasitic in the vagina of the cow and causes impaired reproduction. J. Andrews and T. von Brand[1] carried out some quantitative studies on glucose consumption by *T. fœtus* during cultivation, and then also found that a gas, which burned explosively when mixed with air, was produced by the organism when growing in serum broth with 0·1 per cent glucose. This fact suggested that it might be hydrogen.

Table 1. COMPOSITION OF THE GAS EVOLVED DURING ANAEROBIC CULTIVATION

Exp. No.	Gas evolved (ml.) per 50 ml. medium	Gas analysis (per cent) Carbon dioxide	Oxygen	Methane	Hydrogen	Nitrogen
1	10·0	0·00	1·77	1·89	83·73	12·61
3	9·4	0·00	6·00	0·30	73·65	20·04
7	11·9	1·96	5·57	2·05	78·65	11·77

We cultivated *T. fœtus* anaerobically in a 200-ml. injection syringe with a cock attached to its nozzle so as to catch any gas evolved. Cultivation was in a bacteria-free condition on a boiled beef extract containing 1 per cent peptone, 10 per cent bovine serum, 1 per cent glucose and 0·5 per cent sodium chloride at 37° C. for 48 hr. The gas evolved amounted to 9–11 ml. per 50 ml. culture medium. As shown in Table 1, it was demonstrated by micro gas analysis that the gas contained a large quantity of hydrogen and a small quantity of methane.



Relationship of the evolution of (I) hydrogen, (II–I) metabolic carbon dioxide, and (III–II) carbon dioxide by acid formation in the course of anaerobic glucose breakdown by *T. fœtus* suspension

By using the saline suspension of *T. fœtus*, we further investigated manometrically this hydrogen evolution under anaerobic conditions. In order to differentiate metabolic carbon dioxide from the hydrogen evolved and formation of acid, three flasks (Warburg manometers) were used, of which both flask I, containing 20 per cent potassium hydroxide in the centre well, and flask II, without potassium hydroxide, were filled with nitrogen as the gas phase, and flask III was kept in an anaerobic carbon dioxide–bicarbonate buffering state. We found a gas other than carbon dioxide in flask 1, and estimated the metabolic carbon dioxide evolution by subtracting the volume of gas evolved in flask I from that in flask II, and acid formation by the determination of bicarbonate remaining, as shown in the accompanying graph (in the presence and absence of glucose as substrate). Table 2 shows that this hydrogen evolution depends on the amount of glucose added and not on the peptone, and that it increases somewhat on the addition of pyruvate or formate. These facts suggest that the evolution of hydrogen is connected with the anaerobic carbohydrate metabolism accompanied with acid formation.

Table 2. EFFECT OF SUBSTRATES AND pH ON THE HYDROGEN EVOLUTION

Substrates	Final concentration	pH	Relative amount of hydrogen evolved during 30 min.
Endogenous		7·0	100
Glucose	0·005 mol. 0·01 0·01 0·01 0·015	7·0 7·0 4·8 8·5 7·0	130 234 133 264 280
Peptone	1 per cent	7·0	99
Pyruvate Formate	0·01 mol. 0·01	7·0 7·0	160 128

Further investigations showed that the main end-product of this acid formation is neither lactic nor pyruvic acid, but succinic acid. These results suggest that the anaerobic glucose breakdown differs considerably from the usual glycolytic process.

We are indebted to Dr. C. Koyama for the micro gas analysis.

Helical Thickenings and Micellar Orientation in the Secondary Wall of Conifer Tracheids

THE suggestion that the cytoplasmic surface possesses the capacity to govern the micellar orientation of the cell wall has been made both by Frey-Wyssling[1] and Preston[2], whereas the possible influence of forces arising from cell turgor and protoplasmic streaming have been discussed by Castle[3]

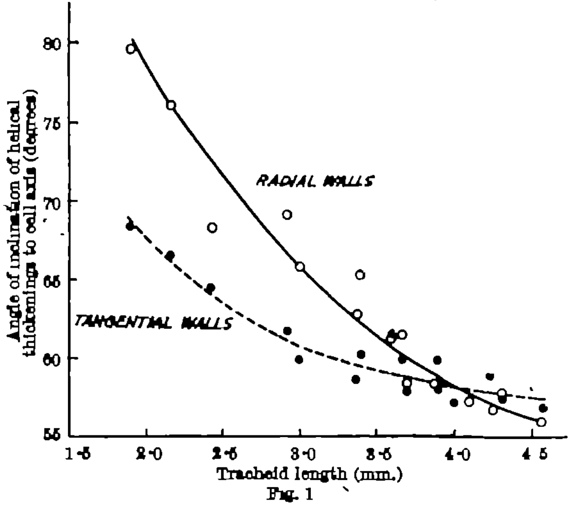

Fig. 1

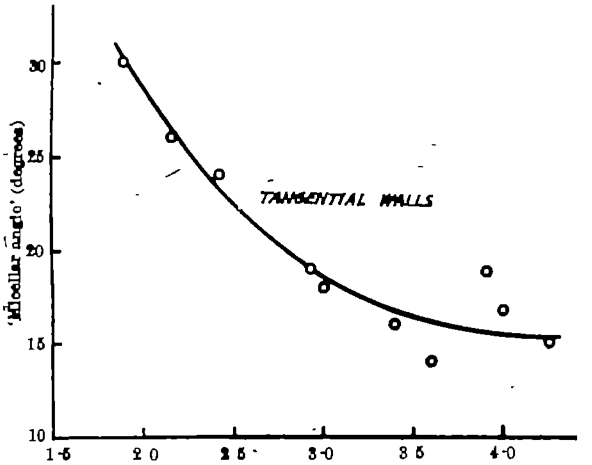

Fig 2

and by van Iterson[4]. Difficulties in technique have prevented any direct experimental proof of either hypothesis. The formation of cell-wall thickenings which are present in the prosenchyma of many plants has, however, been shown by Cruger[5] and others[6] to reflect a structural differentiation in the cytoplasm of a pattern similar to that of the later-formed thickenings, and recognizable upon plasmolysis. In conifer tracheids the phenomenon has been illustrated diagrammatically by Jeffrey[7], although it is not clear whether his diagram was based on direct examination or analogy with other cells. These observations, however, point clearly to the influence of the cytoplasm in governing the orientation of cell-wall thickenings, to the axis of which the micelles of cellulose are parallel[8]. As the thickenings are an intrinsic part of the cell wall, and in view of the cytoplasmic differentiation which precedes their development, it becomes of interest to consider whether further evidence can be obtained to indicate a similar function of the cytoplasm n governing micellar orientation in the cell wall generally.

In conifer tracheids the normal secondary cell wall consists of three layers of different helical micellar orientation such that in the outer and inner layers the micelles make a large angle ('micellar angle') with he longitudinal cell axis, whereas in the middle layer his angle is small[9,10]. A remarkable feature of this organization demonstrated by Preston[11,12] for the middle layer is that the micellar angle becomes less with increasing cell-length, hat is, the helix becomes steeper. It was noted further by Preston[11] that the micellar angle was greater on the radial han on the tangential walls. The relation between cell-length and micellar orientaion has since been demonstrated to apply also to the outer layer of the econdary wall[13] as well as to organizaion of the secondary wall in other cells[12].

The demonstration of a similar relation between cell length and the orientation of he helical thickenings in species in which hey occur could be regarded as support or the assumption that factors which govern the orientation of such thickenings (and of their constituent micelles) lso govern the micellar orientation of he cell wall. Accordingly, a study was made of the variation in the angle of orientation of the helical thickenings with respect to the increase in cell-length which occurs in successive growth-rings from the centre of both stems and branches of conifers. The results obtained for *Pseudotsuga taxifolia* (stem – late wood) are shown in Figs. 1–3. Early wood from the *Pseudotsuga* and late wood of *Taxus baccata* (branch) gave parallel results. The 'micellar angle' of the middle layer of the secondary wall was determined from the spread of the 002 arc of the X-ray diffraction diagrams of the specimens and has been plotted for comparison (Fig. 2). The number of turns per cell of the spiral thickenings was found to increase with cell length (Fig. 3). In both specimens two helices were observed in each cell.

From Fig. 1 it is clear that the change in the angle orientation of the helical thickenings with cell length paralleled that of the micellar orientation of the middle layer of the secondary wall. Furthermore, in *Pseudotsuga*, both in early wood and in late wood tracheids, the angle of orientation of the thickenings was greater on the radial than on the tangential walls, which is a result similar to that obtained earlier by Preston[11] for the micellar orientation in the middle layer of the secondary wall. The suggestion that the angle of orientation of the thickenings is a function of cell wall thickness[14] is not confirmed by the present results, as in both the early wood and late wood of *Pseudotsuga* the change in orientation with increasing cell length was observed with little or no change in cell wall thickness.

If it is assumed that the change in orientation and number of turns of the helical thickenings with increasing cell length reflects a similar and prior differentiation of the cytoplasm, then the change in orientation cannot be attributed to the unwinding of a helically organized protoplast in the ageing cambium. The greater number of turns in the longer cells suggests the synthesis of additional cytoplasmic material, as the dimensions of the cells differentiating from the cambium increased. This is of interest in relation to the concept[15] that helical form may originate from rectilinear growth on the surface of a cylindrical object and may have implications in relation to cases of so-called "spiral" growth of plant cells[16]. Although admittedly of an indirect nature, it is considered that the present observations give added support to the view that the cytoplasmic surface is a major factor in determining micellar orientation and may give some indication of the complex

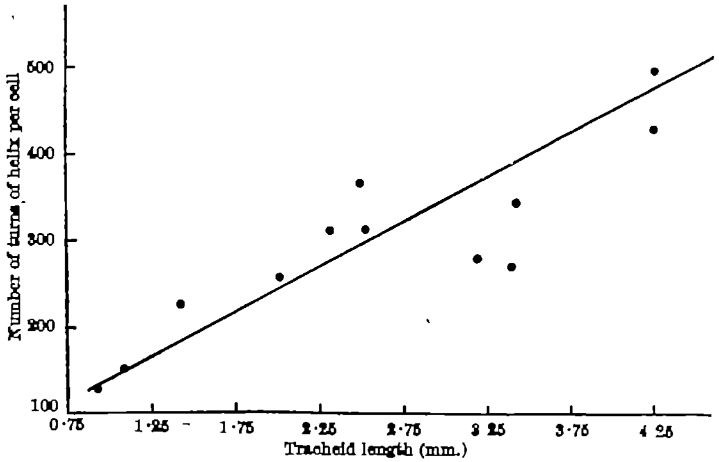

Fig. 3

morphogenic factors involved in the development of the fine structure of the cell wall.

Spermatheca in Sucking Louse

The spermatheca is stated to be absent, by Patton and Cragg[1], in the Anoplura, *Pediculus humanus*, and also by Florence[2] in *Hæmatopinus suis*. But Keilin and Nuttall[3] indicate the existence of a spermatheca in their figure of the reproductive system of *P. humanus*. Qadri[4] disputes this finding and points out that a spermatheca is also absent in *Hæmatopinus tuberculatus*.

On reference to the literature, we find that Mjoberg[5] records the presence of a spermatheca, but only in two species of Anoplura, *Linognathus angulatus* and *Acanthopinus sciurinus*, and gives a brief description of the structure of an empty spermatheca. Ferris[6], in summing up the generic character of *Linognathus* End, mentions the presence of a spermatheca, the opening of which is marked by a sclerotic scar. In view of discrepancy regarding the existenc of a spermatheca in sucking lice, we have examine a few related species. We find that the spermathec exists in the cow-louse, which we provisionall identify as *Linognathus vituli* (Linn.). But th structure is quite different from that given b Mjöberg, in so far as there is no chitinous disk o the spermatheca near the origin of its duct, nor i there any sclerotic scar as mentioned by Ferris. Th spermatheca in this species is a large club-shape sac, bent in the middle and lying to the left of th median line. It opens dorsally into the vagina, b a short duct (Fig. 1). The spermatheca, in one ou of ten specimens, contained oval-shaped spermatophores, varying in number from one to eight. In th photomicrograph (Fig. 2) a single spermatophore i shown within the spermatheca. In the majority o cases the spermatheca is empty. The shape of th spermatheca changes as it becomes distended wit spermatophores. The occurrence of spermatophore within a spermatheca is of special interest, as it ha not been reported by previous investigators, an Wigglesworth[7] remarks that spermatophores are neve transferred to the receptaculum of the female. Th disproportionate number of females to males, namel 3 : 1 in the cow-louse, is noteworthy. We confirm tha the male possesses a tubular seminal vesicle an accessory glands, as pointed out by Mjoberg an others.

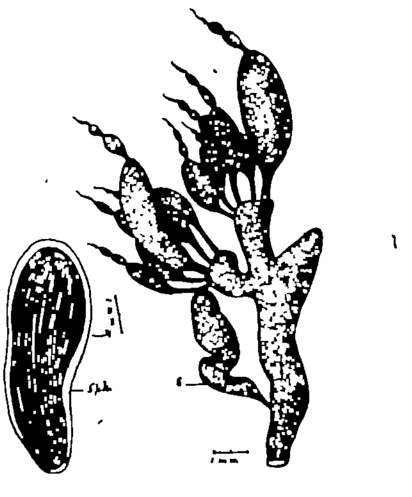

Fig. 1. Female genital system of the cow-louse showing the spermatheca (s). On the left, a spermatophore

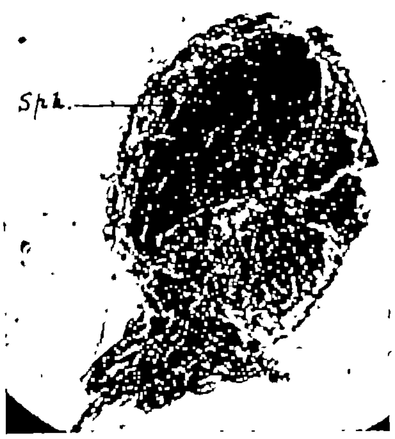

Fig. 2. Photomicrograph of a spermatophore (sph) within the spermatheca

We also wish to record the presence of a spermatheca in the elephant-louse *Hæmatomyzus el phantis* Piag., as there is no mention of it in th descriptions of previous authors.

We wish to thank the Director of the School (Tropical Medicine, Calcutta, for the photomicr graph.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, October 8

Physical Society, Acoustics Group (in Room C4 (East Wing), King's College, Strand, London, W.C.2), at 5.30 p.m.—Mr. P. H. Doak: "The Pulse Response of Auditoria".

Tuesday, October 9

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. Daryll Forde: "Strange Families".*

Chadwick Public Lecture (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 2.30 p.m.—Mr. F. H. Bruce: "Some International Aspects of Environmental Hygiene".*

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.8), at 5 p.m.—Scientific Papers.

Institute of Physics, Education Group (at 47 Belgrave Square, London, S.W.1), at 5.30 p.m.—Prof. A. D. Ross: "Experiences in Education in Science in Australia".

Institution of Chemical Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Discussion on "The Education of the Chemical Engineer by Part-time Study".

Royal Society of Medicine, Experimental Medicine Section (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Discussion on "Aureomycin" (to be opened by Dr. B. Duggar, Dr. J. G. Scadding and Lieut. J. Killough, U.S.N.).

University of London (at the Assembly Hall, Institute of Education, Malet Street, London, W.C.1), at 5.30 p.m.—Prof. E. Adrian, O.M., F.R.S.: "The Scientific Basis of Medicine, 1, The Scientific Approach to Medical Research".*

(Further Lectures on October 11, 16, 18, 23, 25 and 30, November 2, 5, 7, 14, 16, 20, 23, 27 and 29, December 4, 6 and 11.)

Illuminating Engineering Society (at the Royal Institution, Albemarle Street, London, W.1), at 6 p.m.—Mr. J. G. Holmes: Presidential Address.

Textile Institute, Yorkshire Section (at the Midland Hotel, Bradford), at 7.15 p.m.—Mr. R. G. Oversby: "My Impressions of Textile Technical Training, Research and Production in the Textile Industry of the United States of America".

Wednesday, October 10

Society of Chemical Industry, Microbiology Group (at the Institution of Structural Engineers, 11 Upper Belgrave Street, London, S.W.1), at 2.15 p.m.—Symposium on "The Use of Isotopes in Microbiology".

Institute of Petroleum (at Manson House, 26 Portland Place, London, W.1), at 5.30 p.m.—Symposium on "Acid Sludge—its Utilization and Disposal".*

Thursday, October 11

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Mr. D. R. Newth: "Lamarck and Neo-Lamarckism".*

University of London (at the London School of Economics and Political Science, Houghton Street, Aldwych, London, W.C.2), at p.m.—Prof. Ronald S. Edwards: "Industrial Technologists and the Social Sciences". (Inaugural Lecture.)*

Institution of Electrical Engineers (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Sir John Hacking: Inaugural Address as President.

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 6.30 p.m.—Dr. R. G. Richardson: "Acoustics in relation to Radio Engineering". (Members of the Acoustics Group of the Physical Society are invited.)

Manchester Literary and Philosophical Society (at Whitworth Art Gallery, Manchester), at 7.30 p.m.—Dr. H. A. Thomas: "Development and Design with Man-made Fibres".

Friday, October 12

Association of Applied Biologists (at the Royal Entomological Society of London, 41 Queen's Gate, London, S.W.7), at 11 a.m.—"Insect Physiology in relation to Applied Biology".

Oil and Colour Chemists' Association, Manchester Section, at the Grand Hotel, Aytoun Street, Manchester), at 2.30 p.m.—Discussion on "The Report of the Light Fastness Committee of O.C.C.A." (to be opened by Dr. J. G. Gillan and Mr. F. A. Walker).

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Scientific Papers.

Royal Institute of Philosophy (at University Hall, 14 Gordon Square, London, W.C.1), at 5.15 p.m.—Sir Henry Cohen: "The Status of Brain in the Concept of Mind" (Manson Lecture).*

Saturday, October 13

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. J. W. Jones: "The Spawning of the Atlantic Salmon".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer (with a degree in pharmacy, physiology, pharmacology or medicine) in the Department of Pharmacology—The Secretary, School of Pharmacy, 17 Bloomsbury Square, London, W.C.1 (October 13).

Assistant Physicist (with an honours degree in physics or allied subject) in the Physics Department—The Clerk to the Governors, St. Bartholomew's Hospital, London, E.C.1, endorsed 'Physicist' (October 13).

Research Assistants with electrical engineering knowledge (to at least Higher National Certificate standard) and experience of, or aptitude for, training in measurements in the field—The Secretary, National Institute of Agricultural Engineering, Wrest Park, Silsoe, Beds (October 13).

Scientist, Grade III (with an honours degree in either geology or botany) in the Coal Survey Laboratory, Sheffield, for work on the palæobotany of coal and the correlation of seams—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/374 (October 13).

Scientists, Grade III (with a good honours degree in chemistry, experience in analytical technique desirable) in the Laboratories at Chester and Newcastle-upon-Tyne—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, endorsed TT/376 (October 13).

Technical Officer II (temporary, with a good honours degree in geography or geology) for work in the employment service of the Technical and Scientific Register, dealing mainly with graduates in geography, geology and psychology—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting G.335/51 (October 13).

Graduate Chemist (with biochemical training or interest) to assist in a programme of research on nucleoproteins and allied problems—The House Governor, Royal Cancer Hospital, Fulham Road, London, S.W.3 (October 15).

Lecturer in Glasshouse and Flower Crops, and an Assistant Lecturer in Machinery—The Principal, Kent Horticultural Institute, Swanley, Kent (October 15).

Research Fellow to work in the Department of Metallurgy on theoretical problems concerning the structure and properties of metals—The Secretary, The University, Edmund Street, Birmingham 3 (October 15).

Vice-Chancellor of the University of New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 15).

Aeronautical and Mechanical Engineers (Experimental Officer grade) mainly in the aerodynamics and structures departments at the Royal Aircraft Establishment, South Farnborough—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting C.572/51A (October 20).

Assistant Experimental Officers to train in London as weather forecasters, for services mainly at airfields in the United Kingdom—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.260/51A (October 20).

Chemical Engineers (Principal Scientific Officer grade), with a first- or second-class honours degree in chemical engineering, at a Ministry of Supply research and development establishment, initially in North-West England—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.651/51A (October 20).

Chemist (male) for the post of War Department Analyst (Food Supplies), to take charge of the chemical laboratory at the Army Supply Depot, Singapore—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.657/51A (October 20).

Consultant to take charge of and develop a consultant service to advise commercial and industrial concerns, learned societies, etc., on the establishment and efficient conduct of technical information services and specialized libraries—The Director, Aslib, 4 Palace Gate, London, W.8 (October 20).

Electrical and Mechanical Engineer in the Public Works Department under the Government of Cyrenaica—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting D.429/51-O A. (October 20).

Lecturer in Surveying in the Mining Department—The Registrar, The University, Leeds 2 (October 20).

Mathematicians at a Ministry of Supply research and development establishment in the South-East of London. Senior Experimental Officer or Experimental Officer to take charge of, organize and build up a small computing section, and an Experimental Officer or Assistant Experimental Officer, with interest in applied mathematics or numerical analysis—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.254/51A (October 20).

Research Assistant (with a good honours degree in physics or physical chemistry) for work on the physical and chemical aspects of selective flotation—The Registrar, The University, Leeds 2 (October 20).

Senior Scientific Officer (with a first- or second-class honours degree in engineering, hydro (or aero) dynamics and/or in physics, or an equivalent qualification) at the Marine Laboratory, Aberdeen, to work in conjunction with the fisheries biologists in studying the effects of modifications of commercial fishing gear and in devising new types or modifications of gear to increase fishing efficiency—The Establishment Officer, Scottish Home Department, Room 364, St. Andrew's House, Edinburgh 1 (October 20).

Research Officer (biochemist) in the Division of Food Preservation and Transport, Commonwealth Scientific and Industrial Research Organization, to conduct investigations on the biochemistry of muscle, initially with particular reference to the problem of labile sulphur—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting No. 3579 (October 27).

Chemist, Government Metallurgical Laboratory—The Secretary, Southern Rhodesia Government, Rhodesia House, 429 Strand, London, W.C.2 (October 31).

Lecturer in the Department of Economics at Victoria University College, Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 31).

Physiologist (with honours degree in physiology or honours degree in zoology or biochemistry, with physiology as subsidiary subject) for studies in the general field of the environmental physiology of animals in hot environments, and an Experimental Physicist (with honours degree in physics or equivalent) for work concerned with the instrumentational and biophysical aspects of heat exchange in animals—The Secretary, Hannah Dairy Research Institute, Kirkhill, Ayr (October 31).

Principal Scientific Officers in the Mechanical Engineering Research Organization of the Department of Scientific and Industrial Research: Engineer (with experience of research on engineering materials, preferably on the creep and fatigue resistance of metals at high temperatures) for research into the properties of engineering materials at high temperatures, and an Engineer (with experience of the application of research in industry) to lead research into generic problems of mechanical engineering in the Division studying lubrication, wear, and the mechanical engineering aspects of corrosion, on such problems as the lubrication of high-speed bearings, reciprocating mechanisms, gears, etc.—The Secretary, Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4079/51 (November 8).

Principal Scientific Officers in the Royal Naval Scientific Service: Physicist (with considerable experience in the development of electronic amplifiers and similar devices, together with a wide experience of magnetic and electromagnetic apparatus and a thorough knowledge of eddy current phenomena in various conducting media) to lead a group of scientists engaged on the development of electric and electromagnetic devices, at the Underwater Countermeasures and Weapons Establishment, Havant; a Physicist able to take charge of a division carrying out applied research in connexion with underwater explosives, gun and rocket blast, and the effect of these on ships' structures, and an Engineer familiar with modern techniques of and theory of structures, to undertake both small and large-scale load strain measurements, and with a sound knowledge of the design investigations and experiments involving the mechanical testing of structural assemblies in steel, at the Naval Construction Research Establishment, Rosyth—The Secretary, Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4080/51 (November 8).

Senior Lecturers in Mechanical Engineering (Thermodynamics and Heat Engines). (*a*) Internal Combustion Engines and Gas Turbines, (*b*) Steam and Refrigeration, at the New South Wales University of Technology—The Agent General for New South Wales, 56–57 Strand, London, W.C.2, stating post applied for (November 12).

Principal Scientific Officer (with a first- or second-class honours degree in physics or engineering, or corporate membership of one of the professional institutions, or able to produce evidence of outstanding qualifications and experience; sound knowledge of the radio valve industry in this country, including manufacturing techniques and the development of commercial radio valves is essential) in the Royal Naval Scientific Service for temporary assignment to the staff of the British Joint Services Mission, Washington, U.S.A.—The Secretary, Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4078/51 (November 15).

Professor of Philosophy, and a Lecturer (Grade I) or Senior Lecturer in Mathematics, at the University of Tasmania—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 15).

Senior Lecturer in Geography at the University of Tasmania—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 15).

Director of the Central Building Research Institute, Roorkee, Uttar Pradesh, India—The High Commissioner of India, General Department, India House, Aldwych, London, W.C.2, quoting No. 474.A (November 17).

Lecturers (2) in Biochemistry at the University of Sydney—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 17).

Chair of Social Studies in the University of Natal, Durban—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 30).

Senior Research Officer in charge of the Microbiological Chemistry Section of the National Chemical Research Laboratory in Pretoria—The South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2 (Pretoria, December 1).

Assistant Lecturer (experienced social worker with university qualifications) in the Department of Sociology, Social Studies and Economics—The Secretary, Bedford College for Women, Regent's Park, London, N.W.1.

Assistant Lecturer (Grade B) in the Department of Mathematics—The Principal, Sir John Cass College, Jewry Street, London, E.C.3.

Assistant Lecturer, Grade B (with a good honours degree in physics or electrical engineering; some industrial or teaching experience in electronics is essential) for Applied Physics, at the College of Technology and Commerce—The Director of Education, City Hall, Cardiff.

Chemist II/Engineer II in the Ministry of Supply, London, for the supply and planning of either ferrous or non-ferrous metals used in the manufacture of aircraft, engines and associated equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.674/51A.

Chemists (Principal Scientific Officer grade), with a first- or second-class honours degree or equivalent in chemistry, with many years responsible research experience in modern methods of analysis of inorganic materials, including microchemical methods, at a Ministr of Supply research and development establishment near London—The Ministry of Labour and National Service, Technical and Scientifi Register (K), York House, Kingsway, London, W.C.2, quotin F.640/51A.

Chemists (Principal Scientific Officer grade), with a first- or second class honours degree in chemistry, or equivalent qualification, witl experience in the field of combustion research, at a Ministry of Suppl research and development establishment in Buckinghamshire, fo work on problems of combustion in solid and liquid propellant rocke motors—The Ministry of Labour and National Service, Technica and Scientific Register (K), York House, Kingsway, London, W.C.2 quoting F.650/51A.

Chemists II and III in the Ministry of Supply, London, for th investigation of requirements for non-metallic materials used in th manufacture of aircraft, engines and equipment, and the assessmen and planning of manufacturing capacity for these materials—Th Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.675/51A.

Chief Hydrological Engineer, and Hydrological Engineers (4), in the Soil Conservation Section of the Ministry of Agriculture, Sudan Government—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, endorsed 'Chief Hydrologica Engineer 4/404' or 'Hydrological Engineer 4/404'.

Departmental Assistant in Poultry Husbandry at the Schoo of Agriculture, Sutton Bonington—The Registrar, The University Nottingham.

Electrical Engineers (Experimental Officer grade) at the Roya Aircraft Establishment, South Farnborough, for work on aircraf electrical generating equipment—The Ministry of Labour and Nationa Service, Technical and Scientific Register (K), York House, Kingsway London, W.C.2, quoting D.425/51A.

Field Officers (2) in a Tsetse Survey and Reclamation tean working in the Southern Sudan—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, endorsed 'Veterinar Field Officer, 4/2202'.

Field Zoologist, Kenya (Ref. 27066/12), to undertake surve work of tsetse distribution, to make ecological studies of tsetse control, etc., a Provincial Tsetse Officer, Tanganyika (Ref. 27059/74) to carry out tsetse surveys and inaugurate all anti-tsetse measure in the province, a Public Analyst, Northern Rhodesia (Ref. 27106 53/51), to perform the normal duties of a Public Analyst, includin toxicology, and a Chemist in Tanganyika (Ref. 27106/36/51), for general analytical work of a development research nature, particular in connexion with agriculture, etc.—The Director of Recruitme (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smit Street, London, S.W.1, quoting the appropriate Ref. No.

Junior Investigator (with B.Sc. or equivalent in metallurg for work on the physical metallurgy of mild steel weld metal—Th Secretary, British Welding Research Association, 29 Park Crescen London, W.1.

Lecturer in Geology, and an Assistant Lecturer in Pharmacognosy—The Registrar, The University, Nottingham.

Meteorological Assistants for service in the Antarctic with th Falkland Islands Dependencies Survey—The Crown Agents for th Colonies, 4 Millbank, London, S.W.1, quoting M.27576 B.

Meteorological Officers (women, with honours degree in mathematics, physics or geography), for special Short Service Commission—The Director, Women's Royal Naval Service, Admiralty, Whitehal London, S.W.1.

Microanalyst to take charge of the Microanalytical Department—The Chairman of the Scientific Committee, Weizmann Institute Science, Rehovoth, Israel.

Physicist to supervise research work connected with the mechanical properties of metals and alloys, including creep, fatigue, corr sion fatigue and stress corrosion, and to be responsible for the inte pretation of results according to modern physical conceptions—Th Ministry of Supply, Division of Atomic Energy (Production), Risley Warrington, Lancs.

Research Officer (Ref. A.31) (with university degree in chemic engineering or physics) for work on problems in connexion with soli fuel fired gas turbines, and an Experimental Assistant (Ref. A.1 for work in connexion with the instrumentation of experiment coal burning equipment, and Research Officers (Ref. A.35) (ma or female, with degree in physics or equivalent) to work on proble in connexion with the use of fuel in domestic appliances wit particular reference to smoke elimination—The Assistant Secretar British Coal Utilization Research Association, Randalls Roa Leatherhead, Surrey, quoting the appropriate Ref. No.

Research Officer (biochemist) for service in Kenya, Tanganyi and Uganda, to be responsible, under direction of medical staff, f chemical work in connexion with testing new drugs on humans, a to assist in dietary surveys—The Under-Secretary of State, Resear Department, Colonial Office, Sanctuary Buildings, Great Smith Stree London, S.W.1.

Scientific Assistant (Analyst) by the East Africa High Co mission for the East African Agriculture and Forestry Resear Organization—The Crown Agents for the Colonies, 4 Millban London, S.W.1, quoting M.27761.G.

Scientific Officer (Chemist) at the Water Pollution Researc Laboratory (Department of Scientific and Industrial Researc Minworth, Birmingham, for work on the effect of temperature on ra of oxidation of organic matter by bacterial action—The Ministry Labour and National Service, Technical and Scientific Register (K York House, Kingsway, London, W.C.2, quoting F.323/50A.

Statistical Officer (who will be responsible for the planning statistical surveys and returns, and for statistical analyses) in th Government Statisticians Department, Gold Coast—The Director Recruitment (Colonial Service), Colonial Office, Sanctuary Buildin Great Smith Street, London, S.W.1, quoting 27297/1/51.

Surveyor (Ref. 27076/23) to carry out special duties in char of levelling in Kenya, and Assistant Surveyors (Ref. 27070/28/5 in the Federation of Malaya—The Director of Recruitment (Coloni Service), Colonial Office, Sanctuary Buildings, Great Smith Stre London, S.W.1, quoting the appropriate Ref. No.

THE BALANCE OF SCIENTIFIC RESEARCH AND DEVELOPMENT

A PASSAGE in the latest report of the Advisory Council on Scientific Policy gives point to misgivings recently expressed as to the possible restriction of national expenditure on scientific research and development. The Advisory Council is already considering the extent to which a policy of restricting such expenditure could safely be pursued; indeed, quite apart from the effect of rising costs, in present circumstances it is clearly imperative that those responsible for the conduct of research in all institutions dependent, like the universities, to any extent upon State support, should look carefully at their programmes with the view of making sure that resources are not being wasted. In a recent press interview in London, Dr. C. A. Thomas, chairman of the Board of Directors of the American Chemical Society, expressed concern as to whether in Britain and in some Continental countries fundamental research is prosecuted to-day as intensively as in the past. Dr. Thomas paid tribute to British excellence in this field and suggested that unless our effort is maintained the Western powers will be seriously handicapped in future.

Dr. Thomas's concern appeared to be prompted at least in part by the fear that political conditions such as nationalization and government monopoly might be inimical to the atmosphere in which fundamental research can flourish, and that bureaucracy might lead to industrial stagnation or atrophy. Whether those fears are well-founded or not—and reports from the Nuffield Foundation suggest they warrant examination—they are doubtless also inspired by the emphasis placed in Great Britain in recent years on our shortcomings in applied research. Sir Henry Tizard's remarks in his presidential address to the British Association in 1948, that the productivity of labour in Britain is far lower than it would be if the results of past research were more resolutely and continuously applied, and his view that it is not the general expansion of research that is of the first importance for the restoration of industrial health, have been widely quoted. It is generally recognized that that industrial prosperity will depend more and more on the continuous application of science to industrial practice. Unless we can raise our standard of technology, unless there are many more men in executive positions in industry whose practical experience has been preceded by a scientific education, we shall inevitably fail to keep our place among the great manufacturing nations.

In the long run, as Sir Henry then pointed out, the expansion of research will fail of its full effect unless at the same time we promote education in the higher branches of technology and unless the technologist takes his rightful place in industry. Sir Ewart Smith's address last year at the Birmingham meeting of the British Association on what was essentially this text made a great impression, and although little has been done in the past three years to implement the expansion of higher technological education, the concentration on this issue may well have suggested to Dr. Thomas that fundamental research in Great Britain is likely to be curtailed so as to permit the expansion of applied or industrial research. Such a view is not, however, supported by the trend of the reports of the Advisory Council on Scientific Policy, in spite of the stress laid on securing the fuller and wider application of existing knowledge. It is widely recognized that the prosecution of fundamental research on an adequate scale and under appropriate conditions is an essential factor in the well-being of every industrial nation, and one which cannot be neglected with impunity. Even when writing under the title "The Neglect of Science", Prof. F. E. Simon, in his recently reprinted essays to laymen, does not suggest that the position in Britain is unsatisfactory, but that the need is rather to ensure that our opportunities and resources for scientific research are fully used.

It is, of course, well to recognize, as Lord Hankey pointed out on August 29 in his Centenary Lecture, under the auspices of the Ministry of Labour and National Service (available from the Ministry), on higher technical and scientific man-power, that when government expenditure on science and technology in its own establishments, universities, technical colleges and the like, reaches its present high level, there is latent danger of starving pure science through too great insistence on immediate and practical results. He did not think that this has happened, or is likely to happen in Britain in the near future, under the present system, but universities must be on guard against the risk. It is one to be watched all the more carefully at a time of financial stringency, when some halt in expenditure, if not actual reduction, may be unavoidable; and the risk is one to be considered in determining the form which the expansion of technological education should take.

As to the necessity for such expansion, there is general agreement, in spite of the competition for resources which the rearmament drive and the deterioration of the general economic situation in the past year or so may involve. Concern to improve the means or even the resources available to secure the application of existing knowledge has not in practice led to proposals to direct resources from the prosecution of scientific research to the application of its results. On the contrary, it is recognized that considerable expansion in both higher technological education and in technical education is imperative. The real questions at issue are the relative scale on which such expansion should take place, and where and how it can most efficiently be achieved.

On those questions Lord Hankey was able to give little guidance in the Lecture just noted. As chairman of the recently reconstituted Technical Personnel Committee, he could not well discuss the future work of that Committee; but its reconstitution should ensure that expansion of technological education will be on the basis of quantitative figures for the supply and demand of technologists and technicians.

It is from this point of view that Prof. A. R. Ubbelohde's contribution to a symposium of articles on postgraduate studies in the *Universities Quarterly* of August is of special interest at the present time. Dealing particularly with scientific research at the universities, Prof. Ubbelohde makes a number of very important points. He recognizes that university policy should seek to foster not only the vitality of individual schools, but also to impart a unifying spirit to all the diverse cells of research and scholarship it embraces; he reminds us, however, first that academic research must maintain its broad contacts with other intellectual activities in the university, and secondly that it should not make inflexible demands which would distort general university provisions for the advancement of knowledge.

These are the considerations which Prof. Ubbelohde applies to the critical review of future university policy in this field. First, almost challenging Sir Cyril Hinshelwood's remark to Section B (Chemistry) at the British Association meeting in Edinburgh, he points out that the failure of the scientific man to take a proper part in university administration may be detrimental to the general educational functions of the natural sciences. Admittedly, it is difficult to find really balanced university teachers of the highest quality; but if scientific men shirk their administrative responsibilities in the university, wasteful and dangerous situations can arise, just as they can when the use of the scientific man in public affairs is neglected.

One consequence in the university to which Prof. Ubbelohde directs attention is the warping of the selection of new staff and the provisions for teaching commitments. On this point he makes several suggestions designed to avoid such distortion and to secure the most effective use of staff for research during the creative years. These may seem relatively minor matters; yet it is only by attention to such administrative detail that we can hope to make the most of our limited resources of man-power, not only in the universities but also in other fields of activity.

Even more important, however, particularly in view of current discussions on higher technological education, are Prof. Ubbelohde's observations on the conduct of very high-cost research in the universities. No really satisfactory location of such research is, in his view, possible within the academic framework, and he urges that research programmes requiring very costly capital equipment should normally be segregated to the appropriate research institute or association. Their location in the universities tends to limit the free choice of research programmes by the universities, leading to the selection of programmes of comparatively poor training value, and limiting the experience of the young research worker as well as the flexibility of the research school around such equipment, and particularly the choice of new senior appointments.

In a technological foundation specially instituted for postgraduate work, mature and adequately paid staff can be engaged to run such high-cost equipment, and a better return of new results can be expected before the equipment becomes obsolete. It should not be difficult to provide access to such apparatus for the universities when necessary.

Prof. Ubbelohde makes the further suggestion that the separation of technologies from the academic community should be made at the postgraduate stage, when really heavy costs of equipment first arise. The risk of advanced work and research at the universities being crowded out by demands of expensive equipment requiring administration of an entirely different type would thus be avoided.

One point on which there is general agreement at the present time is that, even in face of the rearmament drive, much more must be spent on technical education, including higher technological education. It is all the more important, therefore, not only that we should, as the Duke of Edinburgh emphasized at Edinburgh, develop a co-ordinated system of scientific and technological education, lack of which is a prime cause of our failure to produce sufficient trained technologists to meet the urgent needs of scientific development in industry and to provide leaders for the future, but also that we should ensure that the money appropriated is most effectively spent. The policy to be followed should ensure so far as possible that all sources of wasted man-power or equipment such as those to which Prof. Ubbelohde directs attention are avoided.

No such policy can be achieved if excessive tenderness is shown to the prejudices or wishes of individual authorities or institutions: the national interest must prevail over sectional interest, but for reasons given and not by bureaucratic decree. It must be recognized that many parties concerned have already made contributions towards the delineation of the principles on which an agreed policy could be based. At Edinburgh, for example, Prof. J. C. Prescott indicated clearly principles which should determine the scope of university teaching in technology. The Association of University Teachers, in an appendix to its report on the place of technology in the universities, published last May, gave some figures regarding the extent to which technologies are dealt with in British university institutions; these show that the range covered at the Massachusetts Institute of Technology is individually equalled or excelled by Birmingham, Newcastle, Leeds, Liverpool, the Imperial College of Science and Technology and Manchester. Staff-standard ratios are not a function of the size or character of the institution, and may well be influenced considerably by the number of staff employed on full-time research.

The Association draws the further conclusion that in Great Britain the distribution of students among the subjects accords reasonably with the relative importance of the various industries; and, when due regard is paid to the location of industry, duplication of subjects among institutions is not excessive. Further, it considers that the number of technological students in British universities could be substantially increased without seriously disturbing the balance of faculties. It also comments on the extent to which the resources of the technological institutes such as those of Zurich and of Massachusetts are devoted to sponsored research. That was the subject of adverse comment in the report of the recent Committee on Educational Survey of the latter Institute; but there is no reason for supposing that it would seriously warp the work of any such institutions which might be established in Great Britain. Other institutions like the Technical University of Delft are conspicuously free of such influence, and all research is done on their own initiative; but the danger must be kept in mind in considering the expansion of research in the colleges of technology generally, as suggested by Dr. H. J. Cull.

This note from the Association of University Teachers is exactly the kind of survey which should have come independently from the Advisory Council for Scientific Policy. It illustrates once more the imperative necessity for dealing with the expansion of university and higher technological education as a whole, and for placing it under a single competent authority. Moreover, here again we see how closely the research aspect of technological education, and possibly that of teaching also, is linked up with the work of the research associations. It is manifest that the whole problem is one for which the responsibility in our existing organization for research and development rightly falls on the Lord President of the Council, to whom indeed, through the Advisory Council on Scientific Policy, the new Standing Committee on Scientific Man-power is presumably responsible.

The position disclosed by the latest returns from the University Grants Committee for the academic year 1949–50 emphasizes the need for early assessment of the situation as a whole. The expansion of the full-time student population of universities and university colleges of Great Britain to 85,421—the highest ever recorded—as compared with 50,002 in 1938–39, gives no indication of the extent to which the accommodation of the universities is already seriously strained. No significant increase in the student population, the Committee comments, would be possible without the provision of new buildings on a much larger scale than seems practicable in present conditions. This is its reason for regarding any substantial increase in this figure as unlikely in the near future. It might have added that the crowding of lecture rooms gives no idea of the even more serious congestion of the time-tables of the teaching staff. Some halt in expansion must, in fact, be called if standards are to be maintained; and the increasing extent to which students are dependent on scholarships and other forms of financial assistance might well in present circumstances operate to afford the universities a breathing space for consolidation and long-term planning. Meanwhile, it should be noted that the number of full-time students in technology, 10,933, was relatively unchanged from 1948–49 (10,884), although the number of advanced students of technology, included in these figures, increased from 858 in 1948–49 to 953.

Over the past three years, the number of full-time students of technology in the universities, though slightly increasing, has been relatively stable and is now only 12·8 per cent of the total as against 12·9 per cent in 1947–48. The essential point is that policy should be formulated, not by the Ministry of Education or any authority concerned with one segment of the problem, but by some authority carrying a general responsibility, independent and strong enough to resist sectional pressure and to probe *ex parte* statements and capable of taking a balanced view of the requirements of Great Britain in regard to the supply of trained men and women, the resources available for the production of that supply, and the repercussions of the redistribution of the effort demanded upon other national needs; this applies not merely in science or technology but also in other fields. Without such a balanced view and wide responsibility, there can be little hope of a policy or programme which will meet the situation without involving waste of resources in man-power and materials that can ill be spared now, and will be hard to recoup by greater efficiency or productivity in the long run.

NATURAL PRODUCTS OF INDIA

The Wealth of India

A Dictionary of Indian Raw Materials and Industrial Products. Vol. 2, Part 1: Raw Materials. Pp. xx+427. Rs. 25; 40*s*. Vol. 2, Part 2: Industrial Products. Pp. xii+251. Rs. 15; 24*s*. (Delhi: Council of Scientific and Industrial Research, 1950–51.)

In the last two decades of the nineteenth century considerable attention was paid by men of science in India, more especially by Warden and Hooper, to the study of Indian natural products. Much of this important work was summarized by Sir George Watt in his two classics, "A Dictionary of the Economic Products of India" and "The Commercial Products of India". Owing possibly to the rapid development in Europe and elsewhere of synthetic organic chemistry, this interest gradually waned. Only recently has there been a notable revival associated more especially with the names of Seshadri, Siddiqui and Venkataraman.

No doubt the study of Indian natural products will form one of the main subjects for research in the National Chemical Laboratory in Poona, while those plant products which have played so large a part in indigenous medicine will be examined at the Central Drug Research Institute opened last February in Lucknow. On that occasion Sir Edward Mellanby remarked: "It is an astonishing fact that whereas a large part of the plants, from which official drugs in the pharmacopœia are made, are already found in this country, yet many of these drugs are imported in large quantities".

To future research workers in these fields the dictionary "The Wealth of India" will undoubtedly prove of great value. When Parts 1 and 2 of Vol. 1, covering the letters *A* and *B*, were reviewed (see *Nature*, 163, 743; 1949), the view was then expressed that the publication would prove indispensable to all those interested in natural products. This is equally true of the present work, Vol. 2, Part 1, "Raw Materials", and Part 2, "Industrial Products", which have now appeared under the editorship of Mr. B. N. Sastri, who has replaced Mr. B. L. Manjunath.

Part 1, which covers the letter *C*, comprises some four hundred pages and is liberally illustrated with excellent coloured plates and line drawings. It is clearly impossible within the scope of a brief review to refer in detail to the individual articles; but one cannot but be impressed by their high quality, their value being much increased by the numerous references to the original literature. In dealing with agricultural products, not only are details given of the most satisfactory methods for their cultivation, their processing and their chemistry, but also statistics are included of Indian production and exports. In the article on pyrethrins there is an informative table of the effect of this insecticide on the pests attacking Indian crops. In view of the fact that although the spinning mills are in India jute is mainly grown in Pakistan, the lengthy article on this subject is of particular interest, and it is clear that the cultivation of jute in India is being widely extended. It is hoped that this will not be allowed to curtail the growing of foodstuffs in which India is so lamentably deficient. It is natural in a dictionary covering so many subjects that it is not free from errors, and in some cases recent work has been overlooked. This is, however, a very minor defect. The book is beautifully printed and produced, and it is remarkably free from typographical errors. It can be most cordially recommended, and its low price (40*s*.), which must be below the cost of production, should ensure a wide circulation.

Outside India, Part 2, "Industrial Products", will have a much more limited appeal. The articles are very diverse, dealing with such subjects as cotton spinning, clocks, cigars and cigarettes. Perhaps the main interest of this volume outside India will be to indicate how rapidly industrialization is advancing. Naturally there is some overlap between Parts 1 and 2 as, for example, in the articles on camphor; but this is unavoidable. It may be anticipated that this account of Indian industries will act as a catalyst and stimulate the further advance of India as an industrial nation. Like Part 1, Part 2 is well illustrated and its cost (24*s*.) is low.

J. L. Simonsen

CHEMISTRY OF HETEROCYCLIC COMPOUNDS

Heterocyclic Compounds

Edited by Robert C. Elderfield. Vol. 1: Three-, Four-, Five- and Six-Membered Monocyclic Compounds containing One O, N and S Atom. Pp. ix+703. 88*s*. net. Vol. 2: Polycyclic Five- and Six-Membered Compounds containing One O or S Atom. Pp. vii+571. 120*s*. net. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1950–51.)

The need for an up-to-date reference book on the chemistry of organic heterocyclic compounds has been widely recognized for some time, and, from several quarters, indications have been given that the need was to be met. The publication of the first two of a projected series of volumes on the subject is consequently a matter of general interest, and Prof. R. C. Elderfield's work will be received with eagerness and carefully scrutinized.

In form, these volumes follow the now familiar pattern of a series of contributions by individual authors under a single editorship. It is the expressed purpose of the authors primarily to present in critical fashion the principles rather than the particulars of individual topics, and to elaborate only in proportion as the lack of monograph or other specialist literature may require. For example, alkaloids receive only incidental mention and, following systematic treatment of simple butenolides, cardiac glycosides are dismissed with a general reference in the appropriate subsection which deals with naturally-occurring derivatives of furan. This policy should commend itself to the reader's purse, although it may not always serve his convenience and will evoke a critical attitude to the use which is made of the space gained.

Volume 1 comprises uncondensed heterocyclic compounds containing one hetero-atom, namely, oxygen, sulphur or nitrogen, in rings of three to six members. This accommodates (Chapters 1–3) discussion of ethylene (and trimethylene) oxides, of ethylenimines and of azete derivatives (azetidine = trimethylenimine) including β-lactams. Furans, thiophenes and pyrroles are assigned separate Chapters (4–6), which are followed (Chapters 7–9) by one on pyran/thiapyran types and by two on pyridines and their hydrogenated derivatives. Tribute must be paid to the authors no less for their clarity of style than for the wealth of information presented. In a composite work of this sort and in a field of this size, expedients of arrangement and occasional rather arbitrary selection of material are inevitable. Biotin, for example, a condensed bicyclic compound, takes up fully a quarter of the chapter on thiophene, whereas this chapter lacks the factual discussion of resonance to make it consistent with analogous sections. Again, the subsection which deals with reduced pyrroles is so severely restricted as to exclude even the mention of proline. Such criticisms, however, are overwhelmed by the merits of the book, which by its modern outlook, its range and readability will command the admiration as well as the interest of both the general and specialist reader.

Volume 2 deals with polycyclic compounds containing one oxygen or sulphur hetero-atom in a five- or six-membered ring. The first five chapters are devoted to the benzo-derivatives of furan, including phthalan and phthalide types, and of thiophene. Thereafter eight Chapters (6–13), all contributed by S. Wawzonek, present the various classes of compound derived from the benzopyran and dibenzopyran systems, the volume being completed by a Chapter (14) on thiochroman derivatives. A consistently high standard of treatment and presentation is maintained throughout, and the assemblage of much material that is otherwise widely dispersed will be particularly welcome. Attention is mainly directed to the fundamental chemistry of the heterocyclic systems, and where naturally occurring compounds are too numerous for detailed consideration, they are briefly described in tables (with references). It is regrettable, however, that these tables and their contents are not mentioned in the index.

Both volumes are well produced. The subject-matter is copiously illustrated with clear-cut, readily intelligible formulæ and is extensively documented by means of footnote references—many of them to recent work—providing a service of inestimable value. As judged by the present volumes, the series is conceived on a generous scale and when completed should go far to meet the requirements of all who have interests in the field of heterocyclic chemistry.

JAMES D. LOUDON

EMBRYONIC DEVELOPMENT IN THE SEED-PLANTS

Plant Embryology

Embryogeny of the Spermatophyta. By Donald Alexander Johansen. (Plant Science Books, Vol. 24.) Pp. xviii+306. (Waltham, Mass.: Chronica Botanica Co.; London: Wm. Dawson and Sons, Ltd., 1950.) 6 dollars.

THE unique range of Prof. Johansen's information on the embryology of the seed plants gives him an obvious authority to write upon the subject. Moreover, there has always been a conspicuous gap in botanical literature in the English language for this book to fill. The author has presented a magnificent compendium of all the recorded observations on embryogeny, largely supplemented by his own researches. It is veritably a mine of information, from which little or nothing, positive or negative, seems to be missing. Indeed, the negative statements are often as valuable as the positive, provided that one bears in mind that such remarks as "nothing is known about so and so" refer only to the author's somewhat strict point of view.

The book is not, however, one which can be recommended for general student reading. It is as a work of reference that it makes its greatest appeal. One should except from this statement the introduction and Chapter 16, "Anthophyta; General Considerations", which deal with the history and scope of plant embryology.

The author has devised a system of algebraic notation for summarizing the sequence of cell divisions during embryonic development, which should be valuable to the research worker as a shorthand method of recording observations. It certainly gives greater precision to descriptions, but if applied too strictly to such plastic material it may prove deceptive. It is certainly difficult to follow without intimate acquaintance.

The first oospore division is taken as the starting-point for description, and therefore fertilization and embryo-sac structure are scarcely mentioned. Although this limitation is in accordance with plan and may have been inevitable in view of the amount of detail presented, it does detract from a rounded presentation of embryology such as is to be found, for example, in Maheshwari's recent book.

On p. 93, the author's plan of embryology is explained under three headings: (1) embryonic morphology, the static aspect or embryography; (2) embryonic physiology; (3) embryogeny, the kinematic aspect, with four sub-divisions—(*a*) embryogenesis, (*b*) embryotectonics, the architecture of the embryo, (*c*) embryogenergy, the destination or functions of the embryo, (*d*) embryonomy, the laws of embryonic development. The book is destined to expound only the last of these four.

The Gymnospermæ occupy eighty pages, while two hundred pages are given to the Angiospermæ, under the name Anthophyta. The families and genera included are compared and related by means of a system of types and variations. The word 'type' has been inherited from Schnarf, and his six type designations, named after exemplar families, have been retained, with one exception. The separation of these types is based primarily on the behaviour of the terminal cell of the two-celled embryo and secondarily on whether the basal cell does or does not contribute to the embryo proper. The classification is simple, clear, and expresses differences of a fundamental nature.

Each type is sub-divided into a number of 'variations'. This term is unfortunate, for it has no genetical implication and is a purely formal expression of certain morphological concordances in embryonomy, grouping together plants which are otherwise unconnected. The term 'sub-type', though cumbrous, would have been better. Better still would have been the word 'pattern', which Johansen himself uses only in the Orchidaceæ, a family more or less *sui generis* embryologically. Terminology is, however, always a bone of contention between British and American authors and need not be further pursued here.

It is a reviewer's privilege to differ from his author; but he must not be ungenerous to his merits. This work has been so carefully compiled and it is so fully documented that it gives a very favourable impression of accuracy and reliability. The book is really a most notable addition to botanical literature, and it will retain its place and value for a long time.

R. C. McLean

HANDBOOK OF ENSILAGE

Silage

By Dr. Stephen J. Watson and Dr. A. M. Smith. (Agricultural and Horticultural Series.) Pp. 143+17 plates. (London: Crosby Lockwood and Son, Ltd., 1951.) 10*s*. 6*d*. net.

THE making of silage is no new thing in British farming. In the last quarter of the nineteenth century it had a considerable vogue, but the science of the process had not been worked out, mistakes were made and results were often disappointing; a few farmers persisted, but, speaking generally, silage-making languished for fifty years. During the Second World War great efforts were made to extend the practice, but these efforts had very little success. By this time much more was known of the changes which occur in green material when it is ensiled, but many farmers had not that knowledge and failed to appreciate that ensilage is merely a method of conservation and that it can never produce good feed from poor herbage. After the War farmers came to realize that the days of cheap imported feeding-stuffs were definitely ended, and not likely to return, and so they were ready to give ensilage a further trial and assign to it its proper important place in their farming systems.

Arable silage plays a part, but it is the ensiling of grass and clover which has been extended so much recently. Grassland provides by far the cheapest food for livestock, but the seasonality of its growth requires that the surplus of spring and early summer should be conserved for winter feeding The established method is haymaking; but this is dependent on the weather, and even in good conditions it entails considerable waste of nutrients. Artificial drying is increasing, but it is very expensive both for equipment and in operation. Ensiling grassland herbage costs less than half that of drying it artificially and, on the other hand, entails little more than half the nutrient loss that accompanies haymaking. It is the appreciation of these simple facts which has led to the remarkable increase in ensilage witnessed in the past two or three years, and it really does seem that the practice is now at last established in British farming.

There is no simple rule of thumb for making good silage. Details of the process must vary according to the material to be ensiled, the silo and equipment available, and to the weather at the time. For success, some knowledge of the principles involved is essential, and hitherto there has been no simple and complete handbook on the subject. Prof. S. J. Watson and Dr. A. M. Smith have met this need and met it very adequately. Their book is written in the plainest language; it deals sufficiently with the underlying principles and exhaustively with the details of the various methods. The book will be welcomed by farmers and by students, and it should do much to consolidate the position which silage-making has newly won.

H. G. Sanders

STUDIES IN ECONOMETRICS

Statistical Inference in Dynamic Economic Models

By Cowles Commission Research Staff Members and Guests. Edited by Tjalling C. Koopmans. (Cowles Commission Monographs, No. 10.) Pp. xv+438. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1950.) 48*s*. net.

THIS book, to which eleven authors have contributed, represents the work which has been done by the members of the Cowles Commission and their collaborators during the past few years on the exploration of economic relationships by statistical methods. It is one of the most important works on econometrics which has yet appeared, and, although it is not easy to read, particularly for the economist with no special mathematical knowledge, it will be widely studied.

The basic problem of econometrics is to set up a model of the economic system and to formulate the equations which determine its behaviour. This raises questions which are distinct in degree and emphasis, though not perhaps in kind, from the parallel problems of writing down the equations of physics. The approach of the Cowles Commission is to formulate a set of linear equations in two kinds of variables: *endogenous*, namely, those inherent in the economics of the system; and *exogenous*, namely, those which impinge on the system from without. The effect of disturbances and the impossibility of experimentation are taken into account by allowing these variables to incorporate a random element. There are then four classes of problem for examination: to set up the system of equations; to determine whether they are soluble; to construct a system of estimation for the unknown parameters; and to compare the results in practical cases to see whether they are plausible enough to justify acceptance of the model.

The basic memoir in this volume is that by Koopmans, Rubin and Leipnik on "Measuring the Equation Systems of Dynamic Economics". The other articles develop various aspects of the subject in dealing with problems of identification, structural and predictive estimation and time-series. The papers, considered as a whole, are of a high standard; but the connectivity of the treatment suffers from the fact that they are by different authors, there is no clear set of definitions of some of the terms employed, and no practical examples are given. This is therefore a book for the specialist. The Commission promises a further volume of a more expository character in which emphasis will be placed on basic ideas and techniques rather than on mathematical proofs.

Colloques Internationaux du Centre National de la Recherche scientifique, 14

Méthodes de calcul dans des problèmes de mécanique, Marseille, 30 Mars–6 Avril 1948, Paris, 8–9 Avril 1948. Pp. 105. (Paris: Centre National de la Recherche scientifique, 1949.) 900 francs; 20*s*.

THE subject of these lectures is more restricted than might be anticipated from their title. The first part of the colloquium was held at Marseilles, where it was hoped to establish a mathematical laboratory, and opened with an appreciation of British methods by J. Valenski (Marseilles). The proceedings consisted chiefly of an exposition of Southwell's well-known 'relaxation method', delivered by D. N. de G. Allen, one of Sir Richard Southwell's colleagues. A later British method, the 'escalator method' of Morris and Head, was explained by T. Vogel (Marseilles); it has roughly the same relation to dynamics as Southwell's method has to statics.

In the second part of the colloquium, held at Paris, M. Picone (Rome) dealt with the analysis of periods, a problem of great importance in astronomy, meteorology, statistics and other branches of science. This problem has been studied by H. and Mme. Labrouste (Paris) and by F. Vercelli (Italy). An account of the 'Logobax' machine which can perform the calculations needed in the Labrouste method was given by L. Couffignal (Paris). J. M. Burgers (Delft) discussed some problems of turbulent motions in fluids. L. Malavard (Paris) dealt with calculations by the aid of electric circuits, and their application to hydro- and aero-dynamics. A. van Vijngaarden (Amsterdam) and F. H. van den Dungen (Brussels) dealt with other methods applicable to hydrodynamics. Finally, L. Couffignal discussed in general terms the role of numerical calculation in scientific and technical research.

The organizers deliberately excluded consideration of mechanical and electronic calculating machines on the ground that a subject so vast would require a whole colloquium to itself. H. T. H. P.

Fluorine Chemistry

Edited by Dr. J. H. Simons. Vol. 1. Pp. xvii+615. (New York: Academic Press, Inc., 1950.) 12 dollars.

"FLUORINE", it has been stated by Prof. N. V. Sidgwick, "is in some ways the most interesting of the halogens." Yet the importance, both real and potential, of the element and its compounds has become apparent only in recent years. Extensive and vigorous researches have occurred since 1940, and have rendered obsolete and inadequate the two classical works on fluorine by Henri Moissan and Otto Ruff. For this and other reasons, the publication of a new and thorough treatise on fluorine chemistry is timely and welcome.

The first volume of this work is written by a group of fifteen authors, each dealing with a branch of the subject in which he has personal experience. The inorganic chemistry of fluorine is described in detail by H. J. Emeléus, A. B. Burg, H. S. Booth, J. T. Pinkston, jun., D. R. Martin and J. H. Simons—special attention being given to the halogen fluorides, boron trifluoride and hydrogen fluoride. The preparation of elementary fluorine—now no longer a laboratory curiosity, but an item of industrial production—is dealt with by G. H. Cady. Some theoretical aspects of fluorine chemistry are examined by George Glockler in one of the more speculative chapters.

Perhaps the most fascinating sections of the book are those by L. A. Bigelow, J. H. Simons, T. J. Brice, W. H. Pearlson, and J. D. Park, in which the fluorocarbons and their derivatives are described. This field is potentially one of the most enormous in chemistry, for the fluorocarbons are not only more stable than hydrocarbons, but form large numbers of derivatives.

Altogether, this is an excellent production, authoritatively written. H. A. SKINNER

Practical Dairy Bacteriology

By Prof. Paul R. Elliker. (McGraw-Hill Publications in the Agricultural Sciences.) Pp. ix+391. (New York and London: McGraw-Hill Book Co., Inc., 1949.) 34*s*.

THIS book, as the preface proclaims, is intended for the elementary student. Bacteriological descriptions of the organisms encountered in the production and processing of milk and the manufacture of dairy products are not seriously attempted. The treatment is mainly technological, and in this respect the book can safely be recommended to the operative and to the student in this field. References abound in all the chapters, but these are, with few exceptions, to American publications.

Flamingo City

By G. K. Yeates. Pp. 210+38 plates. (London: Country Life, Ltd.; New York: Charles Scribner's Sons, 1950.) 25*s*. net.

THIS can fairly be said to be an outstanding bird book. Mr. G. K. Yeates is already well known as a bird photographer; but this work shows that he can also write very well indeed. His chapters on the flamingo colony of the Carmargue do not exhaust the interest of the book, although they are its highlights. Mr. Yeates writes on the other birds of Provence, and we have an insight of the beauty of their colouring and the attractive feature of their lives in that sun-drenched land which has only two disadvantages—the mistral and the mosquito. The strange habits of the pratincole and the domestic happiness of the brilliantly plumaged bee-eater are told clearly and arrestingly. The mind of the reader is indeed held throughout the chapters of the book, so that the author's disappointments and his most exciting moments are shared.

In a book where the illustrations are of so high a standard, it is difficult to single out any specially for praise; but the coloured photograph of the flamingo group on p. 158 is truly magnificent. Scarcely less beautiful are the illustrations (p. 62) of the pratincole on the nest, and of the two bee-eaters on the sand (p. 90). The author has interesting things to tell us of the unusual nesting habits of the flamingo. It does not necessarily nest each year, unless the water-level is to its liking. The food of this large and strikingly beautiful bird is not known with certainty. Gallet, who has studied the flamingo more closely than any other living observer, has advanced the novel and bold theory that the bird feeds on putrid mud. This would account for the nesting of the flamingo in a terrain so saturated with salt as to support no apparent life.

The publishers have done their part of the work admirably, and have produced a book which must add distinction to the library of the owner fortunate enough to possess it. SETON GORDON

A CENTURY OF PHYSICS*

PHYSICS FROM 1850 to 1900

By PROF. E. N. da C. ANDRADE, F.R.S.

ONE characteristic of this great period of physics is the complete dominance of Newtonian mechanics; this dominance does not, it is true, distinguish it from the previous fifty years, but does offer a contrast with the period with which Prof. Born is to deal. What, perhaps, characterizes the period more closely is the way in which Newtonian mechanics was applied outside the field of astronomy, and the mechanics of visible masses in general, to which it had been more or less restricted before 1850. In all the various ether models which were a feature of nineteenth-century physics Newtonian mechanics found expression, as the Newtonian system did, indeed, in all the early atom models. But perhaps its most striking direct expression was in the kinetic theory of gases, the creation and development of which to a high degree of precision is almost entirely the affair of this period.

The period is further characterized by the prominence which electrical forces came to attain and the great generalization of the relation between electric and magnetic forces which, at the hands of Maxwell and Hertz, led to the formulation and triumph of the electromagnetic theory of light. The first establishment of the wave theory of light, by Young and Fresnel, in the early years of the past century, necessarily involved the conception of an ether of space: whereas the light particles of Newton could travel through empty space, the propagation of waves seemed to demand a medium, something in which the waves could travel (I must add, in parenthesis, that Newton's particles had certain wave aspects, so that his theory, like that which prevails to-day, demanded for light mixed wave and particle properties). The ether of space, however, if it is to express the experimental facts, must have very peculiar properties, and the history of physics from 1850 to 1900 is characterized by the extraordinary skill, imagination, mathematical ability and physical credulity used in the construction of ethers. Let us glance at some of the steps by which the ether attained its command over much of the physics of the period in question.

The work of Oersted in 1820 first showed that an electric current produced a force that acted upon a magnetic pole—a magnetic force—and Ampère worked out a beautiful mathematical theory of this effect and of the mutual action of steady currents. Faraday developed the laws of electromagnetic induction in the 1830's and put forward a general theory of electric and magnetic action in terms of lines of force. One great contrast between Faraday's views of what we now call the electromagnetic field (the term 'magnetic field' seems to have been first used by Faraday in 1845, just before the period opens) and the views which were then current is the emphasis which Faraday placed on the part played by the medium. In 1851, when the period opens, he published a paper "On lines of Magnetic Force: their definite character: and their distribution within a Magnet and through space" which gives the results of his mature reflexion and develops the conception of cutting lines of magnetic force in connexion with induced currents. This was against the feeling of his times, especially the feeling of the mathematicians. Airy, the Astronomer Royal, for example, said of a slightly later paper in which Faraday had further developed his views on lines of force, "but I declare that I can hardly imagine anyone who practically and numerically knows this agreement [that between the inverse square law of attraction and observation] to hesitate an instant in the choice between this simple and precise action, on the one hand, and anything so vague and varying as lines of force, on the other hand". That was written in 1855. In the same year Clerk Maxwell wrote his first paper on electricity, an elaborate treatise which occupies seventy-five pages in his collected works, entitled "Faraday's Lines of Force". Here he showed that the conception of lines of force could be made to yield precise mathematical results when suitably treated. He wrote: "By a careful study of the laws of elastic solids and of the motion of viscous fluids I hope to discover a method of forming a mechanical conception of the electrotonic state adapted to general reasoning". This sentence expresses as a particular case the general ambition of the man of science of the period—to find the mechanical characteristics which would endow an ether with the necessary properties. This is probably the only occasion on which, in this short paper, I shall have an opportunity of referring to another characteristic feature of the period, the great development of the mathematical theory of the perfect elastic solid and of the perfect fluid, represented by the work described in the great text-books of Love and Lamb. As for real fluids, Newtonian viscosity was just tolerated; but real solids, which did not obey Hooke's law, or, still worse, which showed plastic deformation, were not mentioned in decent scientific society.

A few years after this first paper Clerk Maxwell developed his project and put forward the electromagnetic theory of light. He used illustrations from the motion of a medium governed by Newtonian laws; for example, he conceived magnetic lines of force as vortex filaments. He introduced the conception of a displacement current: when one plate of a parallel-plate condenser was being charged, something between the plates was being elastically displaced, so that the current was continuous. From his equations he deduced that electromagnetic waves must exist, estimated their velocity, found that it agreed with that of light and concluded, in his own words, "We can scarcely avoid the inference that light consists of the transverse undulations of the same medium which is the cause of electric and magnetic phenomena". This is one of the great unifying discoveries of physics. I can only refer to Maxwell's classical "Treatise on Electricity and Magnetism", which is, in the main, a precise quantitative expression of Faraday's general views. Stresses in the medium play a prominent part. Maxwell deduced the pressure of light, which was later investigated experimentally by Lebedew, Nichols and Hull, and Poynting, and has proved of such importance in connexion with astronomical problems and thermodynamic theory. Poynting's name reminds us of his great theoretical discovery, the Poynting vector.

---

* Substance of three papers read on August 13 before Section A (Mathematics and Physics) of the British Association meeting at Edinburgh.

Following Maxwell, Hertz, having first deduced Maxwell's equations on a different basis, proceeded to realize electromagnetic waves experimentally, by means of the oscillating spark discharge. He invented the resonant circuit. Hertz, followed by FitzGerald and Trouton, showed that all the properties of light, reflexion, refraction, polarization, could be demonstrated with the electromagnetic waves from the spark discharge. This irrefutably established the electromagnetic theory of light. I need scarcely refer to the extraordinary developments that have flowed from Hertz's work.

Meanwhile, the search for a satisfactory mechanical ether continued to occupy many of the great names of theoretical physics. Even if the chief result of all this brilliant and sustained effort was to show that such an ether was impossible, I cannot pass it over without mention. Fantastic values for the elasticity and density of the elastic medium which was postulated by many were worked out. Vortices, mixtures of vortices and irrotational elements to make what Kelvin called a vortex-sponge, an aggregate of vortex rings and other kinds of vortex elements were made to bear cumbrous loads of mathematics which now awaken the kind of wonder evoked by the Pyramids—prodigious labour to enclose a small chamber empty of anything that has significance for us. As late as 1903 Osborne Reynolds published a book of 250 pages on an ether consisting of uniform spherical grains beginning, "By this research it is shown that there is one, and only one, conceivable purely mechanical system capable of accounting for all the physical evidence, as we know it, in the Universe", which reminds one of Newton's "It remains, that from the same principles, I now demonstrate the frame of the System of the World", the only difference being that Osborne Reynolds's statement is the inscription on a tombstone of the dead and forgotten and Newton's is on a triumphal arch. It was with reference to Osborne Reynolds's ether that FitzGerald said "Hard particles are an abomination". It is only of recent times that we have come to accept that the ether is no more than a subject for the verb "to undulate" and that Clerk Maxwell's theory is simply Clerk Maxwell's equations.

We cannot leave this cemetery of dead ethers, however, without recounting one consequence of inestimable importance which the search for a satisfactory ether produced. If there were a stationary luminiferous ether, the motion of the earth through it would appear to have as a consequence that the velocity of light in the direction of motion, as measured by an observer on the earth, should be slightly different from that at right angles to this direction. Albert Michelson, with the collaboration of Morley, undertook the task of trying to establish this difference of velocity by an apparatus based on the interference of two beams of light which had travelled at right angles to one another. The sensitiveness of the method, which was an optical triumph, was amply sufficient to establish the motion through the ether, if the reasoning on which it was anticipated was correct. Everybody knows that the result was negative. This result, supported by the failure of other attempts to detect a motion through the ether, was the only begetter of the first theory of relativity, which graced the early years of the succeeding period.

I should here just refer to the experiments on the velocity of light. They begin in 1840 with Fizeau's toothed-wheel method, much improved twenty-five years later by Cornu. Foucault's rotating mirror method enabled much shorter light paths to be used. Michelson effected great improvements and obtained in 1882 a value 299,853 km./sec., which compares well with the value 299,792 recently obtained by Essen—sixty-five years later—a difference of 1 part in 5,000.

The theory of heat as we know it is, with the exception of Carnot's fundamental work (1824), practically the creation of the period 1850–1900. Perhaps I should also mention as a forerunner Fourier, of the importance of whose work there is no question, but his "Théorie Analytique de la Chaleur" (1822) is a mathematical development, not depending on the nature of the heat which is assumed to pass at a rate proportional to the temperature gradient. The first prime advance to which I will refer is the establishment of heat as a form of energy. Julius Robert Mayer's first announcement, in which he calculated a value of the mechanical equivalent of heat, goes back to 1842 and 1845, just before our period, but it received no recognition, rather the opposite. The date 1850 is remarkable as that on which Mayer, probably as a result of persecution, partly real, partly imagined, jumped out of a window and received severe injuries. It was owing to Tyndall that his work first received due recognition in 1862. Joule it was, however, whose work really established in a convincing manner the equivalence of work and heat and gave an accurate value of the mechanical equivalent. This work extended over the period 1843–78. The experiments on the heat generated by stirring water with a measured expenditure of work are described in all the text-books: what is often forgotten is that Joule also measured the heat generated by the current from a dynamo driven by a measured power; by the compression of a gas; and by the forcing of water through fine tubes. The value he obtained in his best experiments on stirring water (1878) was $4 \cdot 184 \times 10^7$ ergs as equal to a standard (15°) calorie: the accepted value to-day is $4 \cdot 181 \times 10^7$ ergs, a difference of less than 1 part in 1,000. Reference should be made to Rowland's extremely careful determination, which gave the value 4·187.

That the various determinations, made by widely different methods, gave the same value of the mechanical equivalent of heat means the experimental establishment of the first law of thermodynamics, which was explicitly enunciated by Clausius in 1850. At the same time Clausius formulated the second law of thermodynamics, which was independently put forward by William Thomson (Lord Kelvin) in a slightly different form. Clausius and Kelvin may rank together as the founders of modern thermodynamics.

The next fifty years saw the rapid development of the two methods of treating thermal phenomena, one the method of thermodynamics, which makes no assumptions as to the nature of heat but deals with its transformation into work according to general laws, and the other the method of statistical mechanics, which assumes the atomic structure of matter and calculates heat effects and transmutations as statistical averages of atomic events. Clausius introduced the term and conception entropy, to express the availability of energy in a thermodynamic system. The two laws of thermodynamics may be expressed as (i) the energy of the universe is constant;

(ii) the entropy of the universe tends to a maximum. Classical thermodynamics rests on the principles of energy and entropy, both defined without reference to the structure of matter. The introduction of the conception of entropy, which is a one-valued function of the state of a system, is one of the great achievements of our period.

It is impossible here to trace the great developments of thermodynamics that, at the hands of Maxwell, Kelvin, Kirchhoff, Helmholtz, van t'Hoff, Willard Gibbs and others led to results of such importance for physics, physical chemistry and engineering. The foundation of the absolute scale of temperature is one great landmark. The application, initiated by van t'Hoff, of thermodynamics to the study of chemical equilibrium—we may mention, as indicative, van t'Hoff's isochore—founded a new branch of science, which has had immense consequences for industrial chemistry. Willard Gibbs, whose work lies entirely in this period, deserves, perhaps, a special word. When, in 1901, the Copley Medal of the Royal Society was awarded to him, the citation said that he was "the first to apply the second law of thermodynamics to the exhaustive discussion of the relation between chemical, electrical and thermal energy and capacity for external work", which summarizes the chief advances of thermodynamics in the last decades of the century. The phase-rule was one of his achievements. I may, perhaps, quote Einstein's words referring to certain papers which he wrote in 1902 and 1903: "Wenn mir das Gibbsche Buch damals bekannt gewesen ware, hätte ich jene Arbeiten uberhaupt nicht publiziert, sondern mich auf die Behandlung einiger weniger Punkte beschränkt".

The application of thermodynamics to radiation was another step of first importance. It was as long ago as 1884 that Boltzmann showed that, by considerations involving the pressure of radiation, Stefan's laws of radiation—that the total energy of radiation of a black body is proportional to the fourth power of the absolute temperature—could be proved thermodynamically. The introduction of the conception of a black body, or full radiator, by Kirchhoff reminds us of the great services of this man. And a close link between this period and that which follows is furnished by a paper written in 1900 by W. Wien, in which he deduced a general formula for the distribution of energy in the spectrum of a black body. What the development of this problem led to at the hands of Planck is well known: it is fundamental for modern physics.

As an experimental physicist I cannot pass over the brilliant work that established experimentally the distribution of energy in the spectrum of a black body, for this, after all, is what guided theory. The work of Lummer and Pringsheim came right at the end of the century, while that of Rubens and Kurlbaum on the infra-red falls precisely in 1900.

So much—or rather so little—for thermodynamics. Let us look at the other method of approaching the problem, the molecular and statistical. The development of the kinetic theory of gases is a capital feature of the period, and led directly to the more comprehensive statistical mechanics. The only work that comes before 1850 is that of Waterston, which had no influence, as it was not published until 1892! It was Kronig (roughly) closely followed by Clausius (more precisely) who early in our period showed that the simple laws of the pressure of gases could be considered as a consequence of molecular bombardment of the walls of the container. Clausius soon introduced the important conception of mean free path. It was Maxwell and Boltzmann who were responsible for some of the chief mathematical developments of the theory. Maxwell established the formula for the distribution of energy among the molecules: the molecules, moving and colliding at random, have a wide range of velocity—theoretically from zero to infinite—and Maxwell's distribution law tells us what fraction of them have velocities within a given small range, when the gas is in statistical equilibrium. It was, perhaps, Boltzmann who by his method of treatment founded statistical mechanics, of which my colleague will, no doubt, have something to say. In particular, he showed that entropy could be expressed as the logarithm of a probability, and so tied thermodynamics and statistical methods together. Before leaving the subject, I may perhaps refer to Maxwell's astonishing deduction from the kinetic theory that the viscosity of gases is independent of the pressure, which he proved experimentally. This prediction was a triumph for the kinetic theory.

A great advance was made when the behaviour of real gases, as distinct from ideal gases obeying Boyle's and Charles's laws, was investigated both experimentally and theoretically. Regnault and Natterer had established just before our period opens that certain gases deviated from these simple laws. It was in 1869 that Andrews published his classical work on carbon dioxide, which established the existence of a critical point and made it clear that gases can be liquefied only if below a certain temperature peculiar to each. A few years later J. D. van der Waals developed his theory of real gases in a paper entitled significantly "The Continuity of the Liquid and Gaseous States in Matter". The theory is epitomized in his famous equation, which he was able to compare with Andrews's results. From it he deduced the theory of corresponding states, namely, that if we express the volume, pressure and temperature of a gas in terms of the critical volume, pressure and temperature of that gas, then one equation without arbitrary or experimental constants expresses the behaviour of all gases. It is not, of course, exact, but approximates surprisingly well to reality. Van der Waals's equation was followed, of course, by many other equations of state, of which the best is probably that of Dieterici.

The work of Andrews and van der Waals was, naturally, of great importance for the problem of the liquefaction of gases: it explained the failure of many attempts to produce liquid gases at a temperature above the critical. In 1883 Wroblewski and Olzewski liquefied oxygen, and soon after Olzewski liquefied oxygen, nitrogen, air and carbon monoxide in large quantities, and saw liquid hydrogen in an evanescent way. Just before the end of the century Dewar liquefied hydrogen in appreciable quantities, making use of his beautiful invention, the vacuum flask. Helium stood out until after the turn of the century; but the Leyden Cryogenic Laboratory, where Kamerlingh Onnes achieved this triumph, was founded by him in 1885. The liquefaction of gases is a good example of how experiment and theory alternate, each experimental stage producing a theoretical advance and vice versa. What modern theory owes to the experimental production of low temperatures is well known; I need only mention specific heats and superconductivity.

Round about 1890 the ether seemed to be the chief outstanding problem of physics: otherwise everything was in very fair order and nice and quiet. The index of *Nature* about that time collects the entries that are taken to refer to the subjects physics and chemistry. Taking two consecutive volumes I find in the index 29 lines referring to physics and about 240 to chemistry, and turning the pages of these volumes seems to show the same peaceful atmosphere in our subject. However, a burst of new discoveries—I do not say entirely unheralded—was about to break upon the scientific world. In his presidential address to Section A at the Edinburgh meeting of the British Association in 1892 Schuster remarked: "The most puzzling fact, however, connected with the discharge of electricity through gases"—a subject that interested him—"consists in the absence of symmetry at the positive and negative poles". That was the key to one great advance about to be made, the discovery of the electron as the result of the study of the low-pressure discharge.

As early as 1874 Johnstone Stoney, from the facts of electrolysis, had concluded that electricity was atomic in nature and had later (1891) suggested the name electron for the unit. The history of the actual establishment of the electron is a complicated matter. Perrin established the negative nature of the cathode stream. J. J. Thomson in 1897 showed that the ratio mass to charge of the particles, if particles they were, was about a thousandth of that for the hydrogen ion in electrolysis, but did not conclude as to the magnitude of the charge. Lenard, from his experiments on the passage of cathode rays through metals, concluded that the particles must be much smaller than atoms. Townsend in 1897 and 1898 attempted a direct determination of the electronic charge and obtained a value about two-thirds of the true figure. H. A. Lorentz showed that the effect discovered by Zeeman in 1897 could be explained on the assumption that the light emission was due to a particle with the properties of the electron. We can say that by the end of the century the existence of the electron was generally accepted, although its charge had not been very well established.

But these last years of the century were full of excitement, full of discoveries which came to full fruition in Born's period. In 1895 Röntgen discovered X-rays, as he named them. further, he himself established with astonishing rapidity their chief properties. They caused a popular sensation by enabling the bones of the human hand to be photographed through the flesh; but in the physical laboratories the ionization which they produced was the chief study. The photoelectric effect had been established by Hallwachs in 1888: in 1899 Lenard proved that the negative electricity released from metals by light consisted of electrons, as independently demonstrated by J. J. Thomson shortly after. In 1896 Henri Becquerel discovered that uranium salts emitted rays which affected a photographic plate, and that it was the uranium atom itself that was responsible for the radiation. This was the beginning of the study of radioactivity. Rutherford's first paper on the subject, which was an impressive piece of work, appeared in January 1899 under the title "Uranium Radiation and the Electrical Conduction produced by it". Meanwhile, in France, Marie Curie had discovered polonium and in 1898 Pierre and Marie Curie made the sensational discovery of radium. In the same year, Schmidt and Marie Curie independently established the radioactivity of thorium. The year after, Debierne produced actinium, and the first emanation, that of thorium, was discovered in the last year of the century. The study of radioactivity was, then, well launched in the early years. Finally, perhaps, if we are speaking of the birth of modern physics, reference ought to be made to the discovery of the positive canal rays, the father of isotopes, by Goldstein in 1886. Corpuscular physics, with its vast possibilities, was born in those last five years of my period.

I realize only too keenly how imperfectly I have surveyed the field. Every physicist here will accuse me, and accuse me with justice, of having made no reference to matters and men of capital importance. I have said, for example, nothing of the great work of Lord Rayleigh on sound—nominally on sound, but the mathematical methods and results exposed in his great book have far wider import, and have, for example, recently been used for problems connected with wave guides. I have said nothing of the discovery of the rare gases, I have said nothing of a vast and significant body of experimental research on heat and light, particularly on spectroscopy: nothing of the determination of the gravitational constant. I can only plead that forty minutes is a short time in which to deal with so much of really prime importance.

PHYSICS IN THE LAST FIFTY YEARS

By Prof. MAX BORN, F.R.S.

THE following review is based on personal recollections and cannot claim historical accuracy and completeness. I shall tell you what has impressed me most, since I attended, in 1901, my first lecture at the University of Breslau, my home city. We were taught what is called to-day classical physics, which was at that time believed to be a satisfactory and almost complete description of the inorganic world. But even Maxwell's theory of the electromagnetic field was, about 1900, not a part of the ordinary syllabus of a provincial German university, and I remember well the impression of bewilderment, admiration and hope which we received from the first lecture on this subject given to us by the then young and progressive lecturer Clemens Schaefer (still active at Cologne).

The first great event of a revolutionary character happened in 1905 with Einstein's theory of relativity. I was at that time in Göttingen and well acquainted with the difficulties and puzzles encountered in the study of electromagnetic and optical phenomena in moving bodies, which we thoroughly discussed in a seminar held by Hilbert and Minkowski. We studied the recent papers by Lorentz and Poincaré, we discussed the contraction hypothesis brought forward by Lorentz and FitzGerald and we knew the transformations now known under Lorentz's name. Minkowski was already working on his four-dimensional representation of space and time, published in 1907, which became later the standard method in fundamental physics. Yet Einstein's simple consideration by which he disclosed the epistemological root of the problem (the impossibility of defining absolute simultaneity of distant events because of the finite velocity of light signals) made an enormous impression, and I think it right that the principle of relativity is connected with his name, though Lorentz and Poincaré should not be forgotten.

Although relativity can rightly be regarded as the culmination of nineteenth-century physics, it is also the mainspring of modern physics because it rejected traditional metaphysical axioms, Newton's assumption about the nature of space and time, and affirmed the right of the man of science to construct his ideas, including philosophical concepts, according to the empirical situation. Thus a new era of physical science began by an act of liberation similar to that which broke the authority of Plato and Aristotle in the time of the Renaissance.

That result of relativity which later proved to be the most important, namely, the equivalence of mass and energy as expressed by the formula $E = mc^2$, was at that time considered to be of great theoretical, but scarcely of any practical, interest.

In 1913 Einstein's first attempt on general relativity became known; it was perfected two years later. It is the first step not only beyond Newtonian *meta*physics, but also beyond Newtonian physics. It is based on an elementary but so far unexplained fact—that all bodies fall with the same acceleration. To this day it is this empirical foundation which I regard as the corner-stone of the enormous mathematical structure erected on it. The logical way which led from this fact to the field equations of gravitation seems to me more convincing than even the confirmation of the astronomical predictions of the theory, as the precession of the perihelion of Mercury, the deflexion of light by the sun and the gravitational shift of spectral lines.

Einstein's theory led to a revival of cosmology and cosmogony on an unprecedented scale. I am not competent to judge whether it was the theory which stimulated the astronomers to build bigger and more powerful instruments, or whether the results obtained with these, like Hubble's discovery of the expanding universe, stimulated the theoreticians to still loftier speculations about the universe. The result, however, is undoubtedly that our astronomical horizon to-day, in 1951, is vastly wider, our ideas about the creation vastly grander than they were at the beginning of the period. We can estimate the actual age of the world (some thousand millions of years), its present size (determined by the receding nebulæ reaching the velocity of light) and the total number of nebulæ, stars and atoms, and we have good reasons for assuming that the laws of physics are the same throughout this vast expanse. The names of Friedmann, Lemaître, Eddington and Robertson must here be mentioned.

But after this boast let me conclude this section on a note of modesty. The fundamental problem of connecting gravitation with other physical forces, to explain the strange value of the gravitational constant, is still unsolved in spite of Eddington's obstinate, ingenious attempts. The most promising idea seems to me that of Dirac, developed by Jordan, that the gravitational constant is not a constant at all, but a scalar field quantity, which like the other ten, the components of the metric tensor, undergoes a secular change and has acquired its present value in the course of time elapsed since the creation of the universe.

Before speaking about the most characteristic features of modern physics, atomistics and the quantum concept, I have to dwell for a short time upon classical physics which, of course, has not suddenly ceased to exist, but continues and flourishes to such a degree that I should venture to say by far the greatest part of the time and effort of physicists is still devoted to problems of this kind, even of those, frequently found in the United States, who believe that nuclear research is the only decent pursuit deserving the name of physics.

In fact, the progress and success since 1900 in ordinary mechanics, elasticity, acoustics, hydro- and aero-dynamics, thermodynamics, electrodynamics and optics is spectacular enough. You have only to remember that in 1900 the internal combustion engine was in its infancy, motor-cars often brought in by horses and the aeroplane a fantastic dream. It would be impossible to attempt even the crudest sketch of these and other technical developments due to physics. Let me only mention a few characteristic points.

The first is the adoption of a more realistic attitude. In the nineteenth century the mechanics of solids and fluids were beautiful mathematical theories well suited for providing examination papers. To-day, they tackle actual problems of daily life and technology, for example, in hydrodynamics, boundary layers, heat transfer, forces on moving rigid bodies like the wings of aeroplanes, the stability of these, even for supersonic velocities. Among the pioneers whom I personally knew are G. I. Taylor, Prandtl, Kármán. In elasticity we have a similar development; the narrow field of problems accessible to analytical solutions has been enormously extended by numerical methods (Southwell's relaxation method), and the results are checked by photoelastic observations on transparent models.

This trend has been strongly assisted by the invention of mechanical and electrical computing machines. The speed and power of the modern instruments based on electronic valves has stirred the imagination of the world and given rise to a new science, cybernetics, the advocates of which expect a revolution of human civilization from these artificial brains—a belief which I do not share.

Acoustics, the branch of elasticity dealing with the propagation of waves, was confronted by numerous problems through the invention of the gramophone, the telephone and broadcasting. Here again the electronic valve was a powerful tool. Ultrasonic vibrations have been used for studying the elastic properties of crystals, for signalling and for time-keeping. The clock controlled by the oscillations of a piezo-quartz crystal seems to be more accurate and reliable than ordinary pendulum clocks.

Prof. Andrade has given an account of the origin and the development of thermodynamics which in 1900 was considered to be complete, with its two fundamental theorems (conservation of energy, increase of entropy). But this complacent conviction was wrong here as in many other cases.

In 1907 Nernst added a third theorem concerning the behaviour of substances at zero temperature. Of its numerous applications to physics and physical chemistry I can only mention the prediction of chemical equilibria and reactions, as exemplified by Haber's method of fixing nitrogen from the air (1914). The experimental approach to absolute zero made great strides. Keesom arrived in 1931 at 0·7° K. with the help of liquid helium. Giauque and MacDougall devised in 1933 a new method for cooling, using the demagnetization of paramagnetic salts. The absolute scale of temperature was extended below 1° K. by Kurti and Simon (1938) and others. Strange phenomena were discovered in this region, the supraconductivity of metals by Kamerlingh-Onnes in 1911, and the superfluidity of liquid helium by Keesom and Wolfke in 1927, Allen and Misener, Kapitza and others.

Even at higher temperatures new phenomena were found, for example, in the field of highly concentrated electrolytic solutions where the names of Bjerrum, G. N. Lewis, Debye and Huckel must be mentioned.

An approach to extreme conditions from another angle was made by Bridgman (since 1905), who systematically investigated the properties of matter under high pressure, reaching more than 100,000 atmospheres. His latest triumph is the observation of the breakdown of the electronic shells of alkali atoms under pressure.

Of great importance seem to me the recent investigations started by Onsager in 1930 and continued by Casimir, Prigogine, de Boer and de Groot, by which thermodynamics is generalized so as to apply to irreversible processes, by combining the classical laws of flow with one single result of statistical mechanics, the so-called principle of microscopic reversibility. The results seem to have a bearing on the understanding of the processes going on in living organisms.

The progress of electrodynamics is obvious to everybody in technical applications: improvements in the production of power and its transmission over long distances; telecommunication methods, such as telegraphy, telephony and wireless transmission. In 1900 electromagnetic waves were a laboratory experiment. Since Marconi's success in 1895 broadcasting has become a powerful factor in human affairs.

Electromagnetic waves comprise the whole of optics, but it would be quite impossible to give an account of the progress in all branches of optical research and practice. The improvements and refinements of all kinds of optical apparatus, of the experimental and theoretical investigation of diffraction, refraction, absorption and scattering are enormous. Let me mention only a few outstanding achievements in spectroscopy because of their bearing on atomic physics: the discovery of the Zeeman and Stark effect, the disentanglement of spectral series by Rydberg, Paschen, Runge, Ritz and others, the Raman effect, the extension of the spectrum towards the ultra-violet and infra-red, and finally the closing of the gap, still existing in 1900, between the longest light or heat waves and the shortest radio waves. The pressure of war helped to develop the method known as radar. In the laboratory it provided the magnetic resonance effect, used for the study of atoms, molecules, crystals (Cleeton and Williams, 1934; Griffith, 1948), and even for the determination of nuclear spin and quadrupole moments (Rabi, 1938). It has also enriched our knowledge of the world at large by the application to the ionosphere (Appleton and Barnett, Breit and Tuve, 1925) and to celestial bodies. Reflexions have been obtained from the moon (U.S. Signal Corps, 1948) and from meteors (Hey and Stewart, 1946), and waves coming from the Milky Way (Janski, 1931) have been observed. This new radio-astronomy will have a profound influence on cosmology.

We now come to atomistics. Although firmly established in the nineteenth century, there were still, in 1900, some distinguished physicists who did not believe in atoms. To-day, such people would be regarded as 'cranks', since the evidence for the atomistic structure of matter is overwhelming.

There are two different but closely interwoven problems to be answered by atomistics: (1) What is the nature of the atoms? (2) How can the behaviour of matter in bulk be accounted for in terms of the collective action of atoms?

Let us begin with the latter question as it has been answered for a special type of matter already in the nineteenth century; I mean the kinetic theory of gases and its extension to more general systems in statistical equilibrium through Gibbs's statistical mechanics. This was in 1900 a reasonable hypothesis. But Einstein's explanation of the Brownian movement in 1904 and Smoluchowski's consecutive work in 1906 provided direct physical evidence for the correctness of the kinetic theory and led Perrin in 1909 to a reliable value of the number of atoms in the gram-molecule.

The theory of compressed gases and condensation started by van der Waals in 1873 has been much improved and modernized by Ursell (1927), Mayer (1937) and others.

A statistical treatment of paramagnetism was given by Langevin in 1905, and extended to ferromagnetism by Weiss in 1907. This was the first example of a type of statistical problem dealing with so-called order–disorder phenomena, to which, for example, the properties of alloys belong. These methods are to-day of great practical importance.

The logical foundations of statistical mechanics were critically examined by Paul and Tatyana Ehrenfest (1911) and its mathematical methods vastly developed by Darwin and Fowler (1922).

While a satisfactory kinetic theory of liquids, in spite of great efforts, is still lacking even to this day, our knowledge of the solid state has been greatly increased. This work is closely connected with research on X-rays. The nature of X-rays was controversial until 1912. Selective absorption and polarization discovered by Barkla in 1909 indicated wave structure. A year later W. H. Bragg found evidence for corpuscular structure. In 1912 Pohl and Walter obtained diffraction at a slit from which Sommerfeld estimated the wave-length. The dispute was finally settled in favour of waves when Laue and his collaborators found, in 1912, diffraction of X-rays by crystals, demonstrating at the same time the atomistic nature of solids, the lattice structure of crystals, which had been hypothetically assumed for a long time.

In the hands of W. H. and W. L. Bragg this method opened a new science, atomistic crystallography, which abounds in ingenious experiments and mathematical considerations, as the systematic application of group theory initiated by Sohnke as early as 1879 and perfected by Schonflies and Fedorow in 1891.

Upon this empirical geometry of crystal lattices there has been erected a dynamical theory which actually started as one of the first applications of quantum theory with Einstein's work of 1907 on the specific heat of solids at low temperatures, and its refinements by Debye and by Kármán and myself in 1910, which, however, has also a large field of application in the classical domain, predicting relations between elastic, thermal and optical properties of crystals. While for a time the ideal lattice was the central object of study, we begin to-day to understand the reasons why actual crystals do in many ways deviate from this ideal pattern.

Many of these investigations are independent of a detailed knowledge of the atoms themselves, using only some crude averages of their geometrical and dynamical properties, like diameter, charge, dipole moment, polarizability, etc.

The problem that remains is to understand these averages; that means, to investigate the nature of the atoms themselves.

The research in the structure of the atom is intimately connected with radioactivity. The discovery of radioactivity belongs to the nineteenth century. Its rapid development is mainly due to one man—Lord Rutherford. He demonstrated the atomistic character of the α- and β-radiation by counting the particles, using first the scintillation method of Crookes (1903), later the Geiger counter (1908). In the later development of counting methods a decisive factor was the amplifying electronic valve, invented in its simplest form (diode) by Fleming in 1904 and improved (triode, pentode, etc.) by de Forest in 1907 and Langmuir in 1915.

Let me mention here some other experimental techniques of great importance which enable us not only to count but also actually to see the tracks of particles: C. T. R. Wilson's cloud chamber (1911) and its refinement by Blackett (1937), the counter-controlled cloud chamber. Then the method of photographic tracks discovered by Blau and Warmbacher in 1937, which through the improvement of emulsions has become a most efficient tool for studying atomic processes.

The first revolutionary results, obtained with the then available primitive experimental technique, by Rutherford and Soddy about 1900, were the laws of radioactive disintegration which shattered the belief in the invariability of the chemical elements. These laws differ from the ordinary deterministic laws of classical physics, being intrinsically statistic and indeterministic.

At the same time ample proof for the existence of isotopes was found among the radioactive elements. Later, in 1913, J. J. Thomson discovered the first example of isotopy among ordinary elements (neon) by electromagnetic deflexion. From here came on one hand Aston's mass spectrograph (1919), the renewal of Prout's hypothesis and the modern version of the Periodic Table with its arrangement of the atoms according to nuclear charge (atomic number Z) as opposed to mass (mass number A); on the other hand, the separation of isotopes in bulk as performed to-day on an industrial scale for the production of fissionable material.

The distinction between these two numbers Z and A is mainly due to Rutherford's second great discovery (1911), the nucleus, obtained through the observation of scattering of α-rays. The result that Coulomb's law is valid down to nuclear dimensions suggested to Rutherford the planetary model of the atom, with the nucleus in place of the sun, and electrons in place of the planets. A welcome confirmation of this was soon (1913) provided by Moseley with the help of X-ray spectra. But formidable theoretical difficulties arose because of the lack of stability of such systems according to the laws of classical mechanics.

In fact, atomic research had reached here a point where progress was not possible without a radical change of our fundamental conceptions.

This revolution of thought was already in progress. It had started in 1900, just at the beginning of this period of review, when Planck convinced himself that the observed spectrum of black bodies could not be accounted for by classical mechanics, and put forward the strange assumption that finite quanta of energy ε exist which are proportional to the frequency, $\varepsilon = h\nu$.

The physical world received this suggestion with great scepticism as it did not fit at all into the well-established wave theory of light. Years passed without much happening. But in 1905 Einstein took up Planck's idea and gave it a new turn; he showed that by assuming the light to be composed of particles, later called photons, a quantitative explanation of the photoelectric effect in metals and of similar phenomena is obtained. Using Einstein's interpretation Millikan (1910) derived from measurements of the photo-effect a value of h in excellent agreement with Planck's original one.

Further evidence for the existence of quanta was given again by Einstein in 1907 through his theory of specific heat, mentioned already, which not only removed some very disquieting paradoxes of the kinetic theory, but also served as a sound foundation of the modern theory of molecules and crystals.

The final triumph of quantum theory was Bohr's application to Rutherford's planetary model in 1913. It solved the riddle of atomic stability, explained the mysterious spectral series and the main features of the periodic system.

Bohr was, right from the beginning, quite clear that the appearance of the quantum meant a new kind of natural philosophy, and so it has turned out. Yet at the same time Bohr was anxious to keep the connexion with classical theory as close as possible, which he succeeded in doing with the help of his principle of correspondence.

There followed a period of about twelve years in which Bohr's ideas were confirmed and developed. Here are a few outstanding events:

Franck's and Hertz's experiments to demonstrate the existence of stationary states with the help of electronic collisions (1914). The disentanglement of the multiplet spectra, including X-rays, by numerous authors, theoretically guided by Bohr and Sommerfeld. Landé's formula for the Zeeman effect (1921) which led finally to the suggestion of the spinning electron by Uhlenbeck and Goudsmit (1925). The confirmation of Sommerfeld's "quantization of direction" by Stern and Gerlach (1921). The refinement of the theory of the periodic system by Bohr himself, confirmed at once by the discovery of one of the missing elements, hafnium, by Coster and Hevesy (1922). Then—most important—Pauli's exclusion principle (1924), which gave a theoretical foundation to important features of observation. Finally, the Compton effect (1923), which demonstrated the usefulness of Einstein's conception of photons.

Thus the paradoxical situation had to be faced that both the undulatory and the corpuscular theory of light were right—in fact, Planck's formula $\varepsilon = h\nu$ states a relation between these contradictory hypotheses.

This challenge to reason came to a climax through de Broglie's famous thesis of 1924 in which this duality wave-corpuscle was, by a purely theoretical argument, extended to electrons. The first confirmation was given by Elsasser (1927) with the help of experiments on electron scattering on metals made by Davisson and Germer (1927), and soon these authors, and independently G. P. Thomson, the son of the discoverer of the electron as a particle, produced diffraction patterns with metal foils which established definitely the existence of de Broglie's waves.

May I mention here in parenthesis that the idea of the electron microscope is considerably older than this theory; it was first suggested in 1922 by H. Busch on the grounds of considerations analogous to geometrical optics. After de Broglie the wave theory of optical instruments became applicable and the resolving power could be determined. I cannot dwell on details, but I wish to remind you that to-day not only bacteria and viruses but even big molecules can be made visible and photographed.

The duality wave corpuscle made an end of the naive intuitive method in physics which consists in transferring concepts familiar from everyday life to the submicroscopic domain, and forced us to use more abstract methods.

The first form of this new method was mainly based on spectroscopic evidence which led Kramers and Heisenberg to the conviction that the proper description of the transition between two stationary states cannot be given in terms of the harmonic components of these states separately, but needs a new kind of transition quantity, depending on both states. Heisenberg's quantum mechanics of 1926 is the first formulation of rules to handle these transition quantities, and these rules were soon recognized by myself as being identical with the matrix calculus of the mathematicians. This theory was developed by Heisenberg, Jordan and myself, and independently, in a most general and perfect manner, by Dirac.

Again, independently Schrödinger developed in 1926 de Broglie's wave mechanics by establishing a wave equation valid not only for free electrons but also for the case of external fields and mutual interaction, and showed its complete equivalence with matrix mechanics.

Concerning the physical interpretation, Schrodinger thought one ought to abandon the particle conception of the electron completely and to replace it by the assumption of a vibrating continuous cloud. When I suggested that the square of the wave function should be interpreted as probability density of particles, and produced evidence for it by a wave theory of collisions and other arguments, I found not only Schrodinger in opposition, but also, strangely enough, Heisenberg. On the other hand, Dirac developed the same idea in a mathematically brilliant way, which was soon generally accepted, also by Heisenberg who produced a most important contribution by formulating his uncertainty relations (1927). These paved the way for a deeper philosophical analysis of the foundations of the new theory, achieved by Bohr's principle of complementarity, which replaces to some degree the classical concept of causality.

In a very short time the new theory was well established by its successes. I can mention only a few points: Pauli's matrix representation of the spin and Dirac's relativistic generalization (1928) which led to the prediction of the positron, actually found by Anderson in 1932. Then came the systematic theory of the electronic structures of atoms and molecules and their relations to line and band spectra, to magnetism and other phenomena. Wigner showed in 1927 how the general features of atomic structures could be found with the help of group theory. Hartree, Fock, Hylleraas and others developed numerical methods. The theory of collisions of atoms with electrons and other atoms was started by myself and developed by Bethe, Mott, Massey and others, from which finally sprang a general theory of the penetration of particles through matter by Bohr.

Further, the derivation of the nature of the chemical bond, initiated by Heitler and London in 1927, was worked out by Hund, Slater, Mulliken, Pauling and others. Even the complicated phenomena of reaction velocities, including catalytic acceleration, have been reduced to quantum mechanics.

Finally came Dirac's most important theory of emission, absorption and scattering of electromagnetic radiation which led to the first systematic attempt of formulating quantum electrodynamics by Fermi, Jordan, Heisenberg and Pauli (1929), and later to the general theory of quantized fields and their interaction (Wentzel, Rosenfeld, from 1931).

The last period of our fifty years is dominated by nuclear physics. Although the importance of nuclear research is probably greater than that of any other branch of physics, I shall be rather short about it for it is the most recent phase of our science and scarcely yet history.

The first breaking up of a nucleus was achieved by Rutherford in 1919, by bombarding nitrogen with α-rays. Artificially accelerated particles were first used by Cockcroft and Walton in 1930. At that time the nucleus was believed to be composed of protons and electrons. But this led to difficulties if one tried to derive the angular momenta of nuclei from the spins of the component particles. In 1932 Chadwick discovered the neutron, and those difficulties disappeared if the nucleus was assumed to consist of protons and neutrons, or charged and uncharged 'nucleons'. Fermi showed in 1932 that neutrons are most efficient in disrupting nuclei as they are not repelled by the nuclear charge. Many of the residual nuclei were found by Irene and Frederic Joliot-Curie in 1934 to be radioactive themselves.

The continuous β-ray spectrum offered great difficulties to the understanding until Pauli, in 1931, suggested the existence of the neutrino and Fermi developed, in 1934, the neutrino theory of the β-decay where the laws of conservation of energy and momentum are preserved. The line spectrum of β-rays was recognized to be of secondary origin, namely, due to the expulsion of electrons from the electronic cloud by γ-rays emitted by the nucleus.

The need for fast projectiles was first supplied by the use of cosmic rays. These had been discovered by Hess already in 1912 and their study has grown to-day into a vast science, covering not only nuclear physics but also geophysics, astronomy and cosmology.

The artificial production of fast particles has made enormous strides through the construction of powerful accelerating machines, as that of van der Graaf (1931), Lawrence's cyclotron (1931), Kerst's betatron (1940) and combinations of these, like the synchrotron.

The clue to the interpretation of nuclear transformations is Einstein's formula $E = mc^2$, or more precisely, the relativistic conservation laws of energy and momentum. I am not an expert in the new awe-inspiring science of nuclear chemistry and shall make no attempt to describe it. I can say only a few words on the theoretical problems of nuclear physics. It is remarkable how many important facts can be understood by extremely simple models, as, for example, Gamow's crater model (1928), which explains the α-decay and the Geiger–Nuttal relation between α-energy and life-time; and the liquid-drop model, suggested by von Weizsacker in 1925, to explain the mass defect (nuclear energy) curve and later used successfully by Bohr (1935) to explain the mechanism of capture, re-emission and fission. A great amount of work has been done on exact quantum-mechanical calculations of the structure and properties of light nuclei (in particular the deuteron) and of the effect of collisions, with the aim of learning something about the nuclear forces. Important results have been obtained, but altogether the situation is not satisfactory.

Quite independently of detailed theories, the empirical values of the nuclear masses (internal energies) indicate that the light nuclei have the tendency to fuse, the heavy ones to disintegrate; hence all matter, except the elements in the middle of the periodic system (iron), is in principle unstable. But reaction velocities are, under terrestrial conditions, so extremely slow that nothing happens. It is, however, different in the interior of stars; Bethe showed in 1938 that one can account for the heat developed in the sun and the stars by a nuclear catalytic chain reaction, the fusion of four nucleons to form a helium nucleus.

The opposite phenomenon, the fission of the heavy nucleus of uranium into almost equal parts, discovered by Hahn and Strassmann in 1938, has initiated a new era in the sociological situation of our science and very likely in the history of mankind. Here is a list of events:

The establishment in 1939 of the possibility of a self-supporting chain reaction by different authors (Joliot, Halban and Kovarski; Fermi; Szillard); the construction of the first nuclear reactor or 'pile' under the direction of Fermi in 1942, and, finally, the harnessing of the industrial power of the United States to produce the atom bomb.

The political and economic implications of this development are too formidable to be discussed here; but I cannot refrain from saying that I, personally, am glad not to have been involved in the pursuit of research which has already been used for the most terrible mass destruction in history and threatens humanity with even worse disaster. I think that the applications of nuclear physics to peaceful ends are a poor compensation for these perils.

However, the human mind is adaptable to almost any situation. So let us forget for a while the real issues and enjoy the useful results obtained from the pile. In physics the remaining few gaps of the Periodic Table have been filled and five or six transuranium elements (among them fissionable nuclei like neptunium and plutonium) discovered. Innumerable new isotopes of known elements have been produced. Some of these can be used as 'tracers' in chemical and biological research, as first suggested by von Hevesy in 1913; others as substitute for the expensive radium in industrial research and in the treatment of cancer.

From the point of view of natural philosophy the most important achievement of the past decade seems to me the discovery of the meson, theoretically predicted by Yukawa in 1935, which showed how far we are still removed from a knowledge of the real fundamental laws of physics. Yukawa became convinced that the forces between nucleons are at least as important as the electromagnetic forces, and by applying the field concepts in analogy to Maxwell's theory was able to predict a new particle which has the same relation to the nuclear field as the photon to the electromagnetic field, but has a finite rest-mass, which from the range of nuclear forces could be estimated to be about 300 electron masses. Soon the existence of mesons was experimentally confirmed in cosmic rays by Anderson and Neddermeyer in 1936 and later with particles produced by the cyclotron in California in 1948. The method of photographic tracks has, in the hands of Powell (from 1940) and others, produced a wealth of new results, for example, the spontaneous disintegration of the meson of about 300 electron masses into a lighter one of about 200 electron masses and a neutral particle. A meson of about 900 electron masses has been fairly well established, and it is not unlikely that still more types exist.

It is obvious that to understand all this a much deeper research in the theory of quantized fields and their interaction is necessary. A revised and modernized quantum electrodynamics was published independently by Schwinger in the United States and Tomonaga in Japan in 1947, and from this has sprung a considerable amount of literature, aiming at the elimination of divergence difficulties and calculating effects of higher order, inaccessible to the older theory. A great success was the explanation of an observation made by Lamb and Retherford in 1947, which showed that Dirac's celebrated theory of the hydrogen spectrum is not quite correct. But it becomes more and more clear that all these mathematical refinements do not suffice, and that a far more general theory has to be found, in which a new constant (an absolute length—or time, or mass) appears and which ought to account for the masses found in Nature. I wish to end this outlook into the future with a remark I have recently heard from Heisenberg. We have accustomed ourselves to abandon deterministic causality for atomic events; but we have still retained the belief that probability spreads in space (multi-dimensional) and time according to deterministic laws in the form of differential equations. Even this has to be given up in the high-energy region. For it is obvious that the absolute time interval restricts the possibility of distinguishing the time order of events. If this interval is defined in the rest system it becomes large in a fast-moving system according to the relativistic time expansion (in contrast to the contraction of length). Hence the indeterminacy of time order and therefore of cause–effect relation becomes large for fast particles.

Thus experience again leads us to an alteration of the metaphysical foundations of a rather unexpected kind. In fact, traditional philosophy has provided the leaders of our science, like Einstein, Bohr and Heisenberg, with problems in so far as it failed to supply answers agreeing with experience. I am convinced that although physics free from metaphysical hypotheses is impossible, these assumptions have to be distilled out of physics itself and continuously adapted to the actual empirical situation. On the other hand, the continuity of our science has not been affected by all these turbulent happenings, as the older theories have always been included as limiting cases in the new ones. The scientific attitude and the methods of experimental and theoretical research have been the same all through the centuries since Galileo and will remain so.

PHILOSOPHY OF PHYSICS, 1850–1950

By PROF. H. DINGLE

THE history of physics is recorded in the publications of the recognized scientific bodies; it is there to see, and cannot be altered. Also, except for the most recent part of our period, there is little doubt and no difference of opinion concerning what is most important in that history; our best text-books differ only slightly, if at all, in what they select as now surviving out of the vast output of the past century. Consequently, in listening to Prof. Andrade and Prof. Born we have been listening almost exclusively to the authentic voice of physics itself.

In the nature of the case, my credentials are less firmly established. The published documents to which I can refer scarcely exist: the *British Journal for the Philosophy of Science* first appeared in May

1950. There were, it is true, isolated writings on the subject throughout the century—mostly from men who, having deservedly acquired a high reputation for their contributions to physics, were more or less forced by popular demand to try to interpret those discoveries in philosophical terms. The results in most cases have fallen into the oblivion they deserve. Reading them is something like listening to a spider discoursing on civil engineering or a seagull formulating the principles of aerodynamics. The unfortunate consequence is that in order to give an account of the philosophy of physics during a period of unexampled physical progress I have to depend very largely on what I can deduce from the implications rather than the direct statements of the writings of the time.

Nor does this exhaust my difficulties. It is not easy to express, with the rigour expected of Section A in the year A.D. 1951, even what is meant by the phrase 'the philosophy of physics'. What I propose to do, therefore, is to give a general idea of what I mean by it. By the philosophy of physics, then, I shall mean the general outlook on experience that one adopts, whether consciously or unconsciously, in terms of which he automatically interprets the discoveries and generalizations of physics and gives them meaning. It is the wider framework of conceptions or instinctive beliefs into which one fits the state of physics at any particular time. One may, in principle at least, form such a philosophy in either of two ways. The first is in terms of what I may call *a priori* notions to which one makes the progress of physics conform. Thus, for example, one may start with the common-sense outlook—what philosophers call *naïve realism*—or with a view of the nature of things fundamentally determined by his religious experience and what seems to him its most natural rational expression, or with the supposed laws of movement of society resulting from economic forces, as the Marxists do, or with some other non-physical set of principles, and look on the successive achievements of physics as completing in one direction the description of the world which that philosophy demands. . The other possibility is that of ridding one's mind so far as possible of all such preconceptions, taking the world-picture suggested by physics as one's starting-point, and generalizing it to form the all-comprehensive world-picture into which it most naturally fits.

Until recently, as intellectual history goes, the former alternative was the only possible one. True, the subject-matter of physics—the elementary awarenesses of movements, of heat and cold, of sound and sight, and so on—were among the earliest and most immediately noticeable elements of our experience; but for that very reason it was imperative to attain to a purely practical, rather than a strictly rational, understanding of them in order merely to survive. The luxury of calm, philosophical contemplation could be indulged best in those realms now given over to psychology and biology and even to phenomena scarcely yet generally recognized as ripe for scientific exploitation—with the result that of what we now call physical laws of Nature, nothing was known before the seventeenth century, and what was thought to be known was but a subsidiary element of a great world-scheme that owed its primary inspiration to other things. But now the situation has changed. The new attitude to philosophy which was inaugurated by Galileo and developed by Newton has spread so rapidly and brought within a few general principles such a vast body of physical experience that no one, whatever his predilections, can fail to recognize that it forms by far the largest and most comprehensive homogeneous body of rationally organized knowledge that we possess. If a stranger to our planet and to our whole type of experience were suddenly endowed with the power of observation and fully developed rational thought, and were to examine the systems of knowledge which we have through the ages succeeded in building up, he could not fail to notice that in magnitude, in coherence, and in the certitude that comes from general agreement, the physical scheme is overwhelmingly ahead of all others. If he wished to obtain a complete rational co-ordination of his experience he would inevitably choose physics as his starting-point, and pursue the path through physics to philosophy.

This fact, however, was only just beginning to be realized about a hundred years ago; it is far from being generally realized yet. During the Middle Ages the predominant world-picture was compounded of elements drawn from Greek philosophy and speculation and Christian dogma, and into that picture such discoveries as were made were fitted without fatal distortion. The scientific revolution of the early seventeenth century coincided with a philosophical revolution, led independently by Bacon and Descartes, which resulted in the substitution for the medieval scheme of what may be called common-sense philosophy, in that it took for its fundamental dogma the Cartesian division of the object of investigation into extended things and thinking things, or, briefly, matter and mind. Of these, when Galileo and Newton had shown the way, matter was relatively easy to study, mind almost impossible. The result was that the physicists, who were the successful explorers of Nature, tended to leave mind out of the field of things to be investigated and to regard it simply as the means of investigation. The world, then, was the world of matter—or of *substance* as, by adoption of a scholastic term, it came to be called. Its constituents moved about in space and time, which accordingly could, in a sense, be called a part of the world, though not a part needing any particular attention. Euclid had once for all formulated the laws of space, and time was obvious enough, so one could devote his whole attention to the nature of matter and the laws of its behaviour. The so-called 'scientific method' of Galileo and Newton was, as its name implied, a means of studying this material or substantial world. It had at its command two instruments—observation, in the form of experiment (that is, observation under controlled conditions), and reason, usually in the form of mathematics.

This philosophy, as I say, was a common sense philosophy. It was derived, not from a study of the practice of Galileo, Newton and their successors, but from the age-long common-sense belief in an 'external world', that 'existed' whether it was observed or not, and that caused observations by acting in one way or another on the sense organs of the observer. The Cartesian dualism was conformable to that belief, which accordingly took on the dignity of a philosophical system but was none the less a simple naïve realism, and so far as men of science were concerned it was for the most part held unconsciously rather than openly acknowledged. Throughout the eighteenth and early nineteenth centuries, men of science were doing things. The question what exactly it was that they were doing did not disturb them; but if asked they would have said they were discovering the contents and laws of behaviour of the external world. They would have been perfectly honest in saying this, and most of them, in fact, would have been astonished if told that any other description of their actions was possible; but it was not a belief arrived at from an actual examination of those actions. The prior existence of the external world was accepted as unquestionable, apart altogether from the practice of science. 'Scientific method' was only a particular way of learning its structure and behaviour—the best way, of course, and perhaps the only trustworthy one, but still just one among others. What physicists were discovering had to be fitted into that framework, and up to the year 1851 at least it found a natural place there without the slightest distortion.

It was roughly about this time, however, that the first explicit attempts to formulate a philosophy of science, starting from science itself, became discernible. I believe the first book to take this as its avowed object was Whewell's "The Philosophy of the Inductive Sciences", which was published in 1840. True, there is little enough in the philosophy of this book that would not have been there had the author been writing as a philosopher of the traditional type rather than as a man of science; but the way in which the ideas are presented does take its shape from the necessity to accommodate the physical science of the time, and one can almost see the author's pen being unconsciously guided by the impulse to exhibit as eternal truth the picture of the world that justified most indubitably the prevailing state of physics. And, indeed, it was not difficult to do this. The Newtonian ideal—that of ascribing all phenomena to precisely specifiable forces acting on a perfectly inert substance according to strictly causal laws—had been uninterruptedly in course of realization; it fitted the Cartesian philosophy so far as material substance was concerned, with the slight difference that the fundamental property of matter, which Descartes had taken to be extension—the power of occupying space—was now thought to be mass; and the method of induction from experiment, which was the hallmark of science, had established its value almost beyond reasonable expectation. One could therefore pursue the scientific adventure with complete confidence that it not only conformed to the accepted principles of philosophy, but even confirmed and exemplified those principles.

The subsequent history of physics is the story of the uprooting of that confidence. There are two broad aspects of this process, corresponding to the physical progress that has culminated in quantum theory and in relativistic field physics, respectively, but before describing the effect of these lines of research I ought to mention that, quite apart from the further development of physics itself, the essential inadequacy of the current philosophy was at least suspected by a few physicists because of its unsatisfactory foundations. Newtonian mechanics, for example, indubitably worked, and was able not only to account for the phenomena that came within its scope but also to make predictions of new phenomena which were duly verified—the discovery of Neptune is a case in point; but the fundamental equations of motion, on which the whole scheme rested, involved logical difficulties that could not be regarded without uneasiness by logical minds. Newton's absolute space, for example, could not be clearly conceived, and there were difficulties in framing the second law of motion in a form that did not include a circular argument. Moreover, as the century progressed, the contradictory properties that had to be assigned to the ether to enable it to fulfil its various functions, culminating in those laid on it by Maxwell's electromagnetic theory of light, led some physicists to doubt whether the simple philosophy that represented physics as an objective study of a given external material world was altogether justifiable. Such men as Kirchhoff, Hertz, Mach, Pearson, Poincaré, in their various ways, gave voice to these doubts and expressed the view that the achievements of physics were not properly represented as the discovery of the nature of an external world. The world they were supposed to be elucidating looked irrational, and they did not wish to study the irrational. Accordingly, they sought a re-formulation of the aims and practice of physics that would make sense of what they and their colleagues were doing. But all this had little effect on the progress of physics as a whole. The building was going up and the parts were fitting together perfectly: why bother about foundations? Let the work proceed and leave the first principles to be justified in time by those who cared for such things. The important thing was to press forward, not to trouble one's self about the point at which the process began.

So it came about that the overthrow of the nineteenth-century philosophy of physics was left to be brought about by the development of physics itself. It would scarcely be true to say that the building collapsed. Rather, a point was reached at which progress stopped. Further bricks were coming to hand, but they could not be fitted into the existing structure without disaster; the foundations were not firm enough to support them. As I have said, the trouble arose in two distinct departments of physics—particle physics and field physics, respectively. I can, of course, give only an outline of what has happened, and I will take the two departments separately, though historically their development overlapped. To put the matter briefly, the undermining of the older philosophy came about gradually in particle physics, beginning with the reduction of matter to elementary particles, the acceptance of which became established doctrine about the beginning of our period, and ending with quantum mechanics, which is one of the highlights of its end. Relativity theory, on the other hand, gave that philosophy a sudden death-blow about the middle of the period. Let me take the gradual process first.

The kinetic theory of matter sought to explain all the manifest properties of bodies in terms of the movements of ultimate indivisible and unalterable particles obeying the Newtonian mechanical laws. What particular forces acted on them remained to be found out, but that some strictly specifiable forces did act, to which they were in absolute subjection, was taken for granted, and the mass movements, colours, temperatures, chemical reactions, and all the rest of the sensible reactions of bodies that make up our apprehension of the world, were believed to be derivable from the mechanical behaviour of the molecules, as they were usually called. These molecules were the reality; what was observed was only appearance, and the problem of physics thenceforth was to find out all that could be discovered of the reality.

This could be done, of course, if one could discover the forces acting on the molecules, and the positions and motions of the molecules at some single instant.

Since these things could not be observed, however, they had to be arrived at by inference, and the way to discover them was anything but clear. But a most important discovery was made. It was possible to describe many of the properties of bodies—and especially gases—in terms of molecules without, in fact, knowing anything at all about the behaviour of any single one of them, except that it possessed a few conceptual properties such as motion, momentum, elasticity. Curiously enough, although the molecules were conceived to be the ultimate reality of the material world, they were at first denied the fundamental Cartesian property of matter, namely, extension; they were conceived as Euclidean points. This was later rectified when it was found that the assumption of definite dimensions extended the range of usefulness of the theory, but it affords an interesting illustration of the essential indifference of physicists to philosophical requirements and exemplifies the fact, which I mentioned before, that a highly abstract conception like mass had displaced a manifest quality like extension as the fundamental characteristic of matter.

The result of this discovery was that the development of kinetic theory took a statistical form and was directed to the interpretation of observations (that is, appearances) in terms of the collective behaviour of multitudes of conceptual molecules. Now it is not difficult to see that this was a betrayal of the true mission of physicists according to the accepted philosophy. They were dedicated to the investigation of reality, and that had become the investigation of the nature and behaviour of the molecules; and instead of pursuing that they occupied themselves in showing how their ignorance of reality could be used in order to describe mere appearances. They could account for the temperatures of bodies, their pressures, viscosities, thermal conductivities, and so on—properties which had no meaning when applied to individual molecules but were significant only with regard to groups of many millions of them; and they were pleased with these achievements. What they were doing was finding rational relations between their observations, and using the molecules merely as counters, as dummies, as useful conceptions by means of which to extend the scope of those relations. And so indifferent were they to the incompatibility of their practice with their philosophy that they were for the most part quite unaware that they were doing anything irregular at all. To give an account of the gas laws in terms of molecular movements was a great triumph. If anyone had said: "But we knew those laws before in a much simpler form: you have merely made them abstruse", they would have replied: "No; we have shown what really goes on in the gas". If then their critic had said: "Well, what does really go on? What is the nature of these molecules? Where is any one of them at any particular moment, and how does it move afterwards? Why do the molecules behave as they do and not otherwise?", the reply would have been, "Well, we don't know those things yet, but no doubt we shall some day". If the critic had then persisted: "So what you have actually done is to find a cumbersome, but possibly fruitful, way of expressing relations between appearances, and left reality to look after itself", they would no doubt have said: "Sir, I perceive that you are a philosopher; we are physicists".

The matter, of course, came to a head when means really were found of investigating the nature of individual molecules. They were reduced first to atoms, then to what are called 'fundamental particles'—electrons, protons, neutrons, and a good many more; the number is indefinite. These are now the ultimate realities. And what do we know about them? Nothing. Not only so, but we believe that we have proved that we *can* know nothing. The utmost we can do is to calculate the probability that one of them will be at a given place at a given time. Of the picturable properties that one would expect small bits of matter to have they have none at all. We cannot even count them—that is to say, not that the task is too difficult, like that of counting the stars in a stellar system, but that they do not admit of being counted; they have not the individuality that formerly would have been regarded as so essential a property of a real particle as to be more fundamental than even extension or mass. We can make them serve our purpose of describing the relations between phenomena only by making them obey statistical laws impossible with objects that can be counted individually. We nevertheless do this, and thereby acknowledge the fact that we are no longer interested in 'reality' so long as we can find rational relations between our observations. We are satisfied to say that a particle, once the ultimate reality of the universe, has no individuality, may be anywhere at all, though it is more probably here than there, and has a future indeterminable from our present knowledge, for it observes no causal laws. The pursuit of reality has ended as a greyhound race ends, with the disappearance of the hare underground. And the only intelligible conclusion is that the object of the whole business is not to catch the hare but to run the race. The only philosophy that accords with the whole history of physics is that which represents physics as the establishment of rational relations between phenomena, not the penetration of phenomena to reach a hidden reality that causes them.

Let me turn now to relativity theory. I am, of course, not going to describe the steps that led to it, but only to consider the nature of the problems involved. In accordance with the philosophy of the time, the real material world, whether regarded as consisting of molecules or of gross bodies, was conceived to possess its properties by intrinsic right. Thus its constituents had a size, a mass, a velocity, and so on. These properties could, in principle at least, be determined; one of the objects of physics, in fact, was to determine them as completely as possible. But even if the attempt to determine them was unsuccessful, they unquestionably existed. The mass of a body was such and such, whether we knew it or not; its length was such and such, whether we knew it or not. Now the basic requirement of the theory of relativity was that all these properties were almost completely indefinite. Take any object—a stick of chalk, for example. Its length is, say, two inches or anything at all less than that, according to the velocity which it has, and that velocity can be held to be anything from zero up to the velocity of light. The higher the velocity, the smaller the length, and no one velocity can be said to be more really correct than another. One may be more convenient than another in a particular problem, but it will be less so in a different problem; fundamentally, the chalk may be said to have any velocity at all between the limits I have mentioned, and no one value is truer than another.

Now it happens that all our measurements depend in one way or another on the measurement of length, and the result is that *all* physical properties of a body depend on this arbitrary velocity. Its mass, for example—the fundamental property of the materialistic philosophy—may be anything from a few grams up to infinity. There is no single quantity that is not almost infinitely arbitrary, having no assignable value at all until you have decided how the body is to be regarded as moving, and the choice of that lies entirely with you; Nature has nothing whatever to do with the matter.

This again is now accepted physical belief. It is not something imposed on physicists from without, but something unavoidably arrived at by them in the normal exercise of their practice. In particle physics we saw that while we were learning less and less about the nature of the fundamental particles, we were learning more and more about the relations between phenomena by using the particles as terms of expression. In relativity theory we see similarly that by abandoning all attempts to assign any definite property at all to matter we can learn more and more about the relations between phenomena. We succeed in the practice of physics in the same measure as we fail to honour the supposed philosophy of physics.

There are two ways of dealing with this situation. One is to retain the old preconception that we are investigating the nature of a real, external, material world, and to add that we have discovered that it is essentially mysterious and even self-contradictory. If you do retain that preconception the addendum is, indeed, inevitable; the world *is* mysterious and self-contradictory. Personally, I find this a very unsatisfying view. Not only does it end in complete nescience, but also it takes no account of the very great and positive achievements of physics. I prefer to take those achievements as indicating the true nature of physical investigation, and that means that we must regard physics as the progressive establishment of rational relations between the results of our measurements. From this point of view the quantities with which physics concerns itself are not evaluations of objective properties of parts of the external material world; they are simply the results we obtain when we perform certain operations. They are just as objective, of course, in the sense that we have no ultimate control over them: we perform the operation and get the result that comes, not the result we may wish. But we do not add the unnecessary and, as it turns out, frustrating corollary that they are measurements of a pre-existing material world of which in its essence we can never know anything.

On the whole, the tendency of those who have attempted to formulate a philosophy of physics in the light of the new knowledge has been to combine these alternatives. They have, in the main, had to recognize the logical force of the second, but have been unwilling or unable to give up a belief that has seemed so imperative as to be beyond denial. I have time for only one or two examples.

The late Sir Arthur Eddington is an outstanding one. His tragedy was that he was born too soon and possessed too precocious and retentive a mind. Consequently, the belief that physics was the examination of the external world became so fixed in his consciousness before the quantum and relativity theories arose that, although he immediately recognized their fundamental importance, he was forced to adapt them to beliefs with which they were, in fact, incompatible. Thus, in 1923, in his "Mathematical Theory of Relativity", we find him saying, and even italicizing the statement, that "*a physical quantity is defined by the series of operations and calculations of which it is the result*". There was really nothing more to be said about it; but for the reason I have mentioned he could not refrain from adding that it represented what he called a "world-condition", which was, however, essentially unknowable. The mysteriousness of these world-conditions was emphasized by an example. The distance of a star and the parallax of a star are two physical quantities; but they are so related that they are used alternatively in all our calculations. They therefore, he concluded, represent the same world-condition. But now, if one of two stars has twice the distance of the other it has half the parallax. Is then the world-condition of the first twice or half that of the second, or is any metrical relation between them inconceivable? We do not and cannot know. The world which has these conditions was, according to Eddington, "the mysterious background of phenomena". He could not see that it was precisely the same kind of thing as the "mere names", according to Galileo, or "occult qualities", according to Newton, that flourished in medieval thought and, as Newton expressed it, "put a stop to the improvement of natural philosophy".

About the same time as Eddington was formulating these views the movement that has become known as logical positivism originated on the Continent through the formation of the Vienna Circle and, later, the Verein Ernst Mach, the object of which was to cleanse philosophy of all those elements that the development of physics had shown to be hindrances. In some respects this movement ran parallel to the movement of Eddington's thought; in others, owing to its entirely different background, it took a quite different course. Thus Eddington asserted that only through physical quantities could we represent to ourselves a condition of the world. "Any attempt to describe a condition of the world otherwise," he wrote, "is either mathematical symbolism or meaningless jargon." He accordingly recognized three types of ostensible approach to a description of the world—physical investigation, mathematical investigation, and meaningless chatter. The logical positivists sought precision by avoiding all reference to operations and speaking in terms only of the sentences in which those operations and their results were expressed, but they reached essentially the same three-fold classification; they divided all possible word sequences into synthetic statements (that is, those expressing the results of sense observations), analytic statements (those occurring in pure mathematics, which were regarded as tautologies), and nonsensical statements. The parallel with Eddington is complete; but whereas Eddington in his classification restricted himself wholly to the field of physics and did not attempt to say anything about other realms of experience, the logical positivists applied their principles to sentences about anything at all, and were accordingly led to describe every statement about the subject-matter of metaphysics, normative ethics and (except in so far as it could be reduced to physics) psychology as nonsense. I mention this merely to prevent misunderstanding; but it is not our present subject, and, returning to physics, we may say that Eddington and the logical positivists were very largely in agreement on the implications of its later developments. So far as the external world was concerned, however, they were less tied to tradition than he was, though they seem to have been unable wholly to disregard the traditional way of speaking. Formally they recognized the external world merely as a convenient form of expression, though the convenience became more obvious the further one removed one's self from physics, but when they were not actually discussing the question of its status they accorded it much more than the homage due to mere convenience. They insisted, for example, that the only kind of statements that "tell us anything about the world" are synthetic statements, and one does not easily find any characterization of such statements from which reference to "the world" is excluded.

I will not follow the later developments of logical positivism, which seem to have emphasized the positive rather than the logical side of the programme, because, in spite of much that is valuable in this movement, I think it suffers from a dearth of scientific men and a surplus of philosophers. I say this not with any provocative intention; but simply because it is a fact, and one which shows itself very plainly in the course the movement has taken. The logical positivists are concerned chiefly with the 'verification' of sentences, and take great pains to prescribe as precisely as possible what steps have to be taken to ensure such verification. In other words, the sentence itself is their starting-point, and its verification (or falsification) their goal. But the sentences with which they start are not the starting-point but the goal of the physicist. His problem is to proceed from evidence to conclusion, not to start with a 'conclusion' and prove it. Proof may be impossible, for the observations that constitute the evidence may not be repeatable; but the physicist still has the problem of making deductions from them. Hence, whatever may be called verification in such a case may be essentially different from that relevant when repetition is presumed to be possible.

The logical positivists, furthermore, emphasize the unity of science, by which they mean the thesis that all science is reducible to physics. To the men of science this appears to be an arbitrary dogma. They establish it simply enough, by characterizing all sentences that cannot be expressed in the existing physical or mathematical language as nonsensical. The scientist, it is true, may look forward to the unity of science, but he cannot adopt it as a presupposition; it is something to be, if possible, achieved. For the moment he is content to proceed in the different sciences on independent lines, using independent means of observation and independent concepts. He may hope that in time there will be a synthesis of the physical, biological and psychological sciences, just as the originally independent sciences of mechanics and heat have merged into thermodynamics, and magnetism and electricity into electromagnetism. But that is a hope, not a categorical pronouncement, and the concepts of the unified science may be biological or psychological rather than physical, or possibly concepts which are entirely new.

The most satisfactory statement of the philosophy of physics to which the later developments point seems to me to have been begun by Prof. P. W. Bridgman. Like Eddington he regards all physical quantities as the results of operations, but he does not encumber his thought with the useless world-conditions that Eddington had to drag behind him in all his adventurings. Bridgman's work has lain mainly in a progressive revision of all physical concepts in order to ensure that they represent no more and no less than particular precisely describable and practicable operations. The necessity for this work can be realized when it is remembered that the whole theory of relativity arose from the discovery that the concept of absolute simultaneity of events at different places corresponded to no practicable operation. In one respect, however, I think he goes too far, and in another not far enough. He applies his analysis to all physical concepts, whether they are employed as the terms in which physical results are expressed or only as instruments to facilitate the attainment of those results. For example, he examines equally the operational meaning of the concept of viscosity and the concept of action at a distance, and is prepared to brand either concept as illegitimate if the corresponding operation is not discoverable. I admit the necessity for this so far as viscosity is concerned, for that is represented by a symbol in physical equations, and the meaning of those equations is indefinite so long as the operations of which its terms are the products are unknown. But action at a distance is not represented by a symbol in any physical equation. It is merely a concept which enables us to picture the situation represented by the equation in such a way as to suggest what next to do. It may fulfil this function whether it corresponds to an actual operation or not, and since, having discarded the external world, we are in no danger of thinking it the 'truth' about Nature, I see no reason for proscribing it if it serves our purpose.

On the other hand, Bridgman stops short just where, from the wider point of view of science as a whole, his ideas could be most valuable. It is true that every physical concept should correspond to a particular operation—indeed, to an operation of measurement, that is, an operation that yields a number, for physics is definable as the science of such operations. It is essentially an experimental science, where we pay attention only to observations made under narrowly prescribed conditions. But most of our experience is not so carefully prepared for; it comes to us automatically, whether we seek it or not, and the wider task of science is that of finding relations not merely between experiences that we go out of our way to obtain, but between the whole of our experiences. That opens up the larger field that, as I said at the beginning, I regard as belonging to the philosophy of physics.

I think it is one of the most satisfactory features of the modern view, expressed best in Bridgman's form, that it allows of the generalization we need. When physics is regarded as the study of the external world, and the world is regarded as a distribution of matter in time and space, there is little room left for anything else except illusions. But when the external world is forgotten, and physics is recognized as the finding of relations between certain artificially acquired experiences, the generalization becomes inevitable that science as a whole is the finding of relations between all elements of our experience. It is not that the question of the existence of the external world is considered and answered in the negative: the question is seen to be irrelevant and not considered. When I am asked whether I believe in the existence of the external world, I promise to reply when I am told precisely what is meant by the external world and by its existence. I have not yet been called upon to redeem the promise. The fundamental question is: What exactly is it that physicists are doing? That can be answered satisfactorily only in terms of experience, not of the external world. It is in any event undeniable that all we can know of any world at all must come from our experience of it—not necessarily sense experience alone, but experience taken as a whole. If then we describe the task of science in terms of experience we shall describe it more directly than is possible in terms of an investigation of a postulated world. That might have been realized long ago; the physics of the past century has made its realization inescapable.

THE 250TH ANNIVERSARY OF YALE UNIVERSITY

By Dr. JOHN F. FULTON, O.B.E.
Yale Medical Library

THE year 1951 marks the two hundred and fiftieth anniversary of the founding of Yale University, and under the leadership of its energetic new historian president, Mr. A. Whitney Griswold, the University is marking the occasion by a series of ceremonies.

The idea of establishing an institution of higher learning in New Haven was conceived many years before the College was actually established, having first appeared in the mind of the Rev. John Davenport, an Oxford man, who, with a group of his countrymen, founded New Haven in 1638. But New England was already supporting one College—Harvard—and it was not until 1701 that ten Congregational ministers met together, each bringing a gift of books, and made plans to petition the General Assembly of the Colony for a charter for a College, granted later that year.

Through the efforts of the Connecticut Colony's agent in London, Jeremiah Dummer, more books were soon on their way across the Atlantic from such well-wishers of the young College as Sir Isaac Newton, Sir Richard Steele, Dr. Edmund Halley, Dr. Richard Mead, Sir Hans Sloane, Dr. Richard Bentley, the King's Librarian, and many others. Among these books were a first edition of Newton's "Opticks" and a second edition of his "Principia", *Tatlers* and *Spectators*, the works of the Honourable Robert Boyle, Robert Hooke, Nehemiah Grew, Thomas Burnet, John Woodward, and such others as enable Yale proudly now to boast of the finest collection in America of books and manuscripts of eighteenth-century England—including the outstanding Falconer Madan Collection on the history of Oxford (acquired in 1929).

Our patron, Elihu Yale, was among these early friends of the College. The main facts of his life can be found on his tombstone in Wrexham:

> Under this tomb lyes interr'd Elihu Yale
> of Place-Gronow, Esqr; born 5th April 1648,
> and dyed the 8th of July, 1721, aged 73 years.
>
> Born in America, in Europe bred,
> In Afric travell'd, and in Asia wed,
> Where long he liv'd and thriv'd; at London dead.
> Much Good, some Ill he did: so hope all's even,
> And that his soul thro' Mercy's gone to Heav'n.
> You that survive and read, take care
> For this most certain Exit to prepare,
> For only the Actions of the Just,
> Smell sweet and blossom in the dust.

In addition to books, a gift of East India goods which brought £562 12s. in the Boston market came from Governor Yale and prompted the clergymen directing the destinies of the Collegiate School to change its name to Yale College in 1718 in honour of its generous benefactor. The portrait of King George I, which came with the other benefactions and which now hangs in the Yale Art Gallery, is to-day the earliest portrait in continuous ownership in an institution of higher learning in the United States.

In 1743 the Rev. Thomas Clap, the progressive president of the College who in his twenty-six years in office did much to broaden Yale's stature as an educational institution, "with considerable Labour and Pains, prepared a Catalogue of the Books in the Library under proper Heads so that you may Readily know and find any Book, upon any particular Subject". From this list of the books in the Library in 1742, a room has been arranged in the Sterling Memorial Library known as the 1742 Library, and on the shelves in their original order can be found many of the early volumes. Among the medical texts were works by Cowper, Willis, Freind, Cheyne, Sydenham, Sanctorius, Cheselden, Van Helmont, Harvey and Glisson—a noteworthy collection for any American library of that time. The Cowper was probably the gift of Daniel Turner, a London physician, who gave a number of books to Yale, for he wrote: "I have robbed my own library of a book very valuable beyond all others and now, as I know, not procurrable elsewhere, the Great Anatomy of our Cowper, that with it I might adorn yours". Turner's letter contained a postscript: "If your worships consider me worthy of the doctoral degree of Yale Academy and have the diploma sent me, I shall receive it not only as a sign of your gratitude, but I shall consider it an honour as much as though it had been conferred by another university, though of greater note. Farewell . . . and may your academy flourish." Rising to the occasion, the College authorities conferred on Daniel Turner in 1723 an honorary degree, the first medical degree to be granted in the American Colonies.

From Britain in these early days of Yale's existence came not only material gifts but also encouragement and inspiration for those who were interested in science, particularly in astronomy and mathematics. When in 1802 President Timothy Dwight persuaded the Corporation to establish a chair of chemistry and secured a young barrister, Benjamin Silliman, to fill it, it was to England and Scotland (after a year in Philadelphia) that Silliman journeyed to acquire his scientific knowledge. The contacts he made there at that time with many of the leading men of science, and later his *American Journal of Science*, to which British and Continental scientific men contributed, ensured a steady flow of influence and ideas from across the seas. His son-in-law, James Dwight Dana, who rose to eminence as a geologist, carried on in Silliman's tradition as editor of the journal and in the chair of geology.

Another outstanding Yale man of science well known in Britain and on the Continent was Josiah Willard Gibbs. He was a man of extraordinary capacity—shy and retiring as a personality, but possessed without doubt of one of the most gifted minds and one of the most original intellects of any nineteenth-century man of science. His genius was more promptly recognized in Britain than in America; but we are happy to record that a definitive biography of Gibbs has now been written by one of the last of his students, Lynde Phelps Wheeler, and published by the Yale University Press as one of the several volumes that have appeared on the occasion of the two hundred and fiftieth anniversary.

Yale's first gesture to mark the anniversary occurred at Commencement in June 1951, when twenty-five honorary degrees were conferred on outstanding American scholars (the usual number in a given year is eight or ten). One of these was conferred on a British subject, the distinguished Polynesian anthropologist and physician, Sir Peter Henry Buck, a native-born Maori chieftain who is now director of Yale's Bernice P. Bishop Museum in Honolulu. Another colourful degree-recipient was the ninety-two-year-old philosopher and educator, John Dewey, who was described as representing the "experimental spirit of America". The venerable Otto Loewi, Austrian pharmacologist and Nobel laureate, was also among those who received degrees, as was the psychologist Edward C. Tollman, "valiant defender of the freedom of the mind", lately removed from the faculty of the University of California for having, with many others, refused to sign the loyalty oath. Still another was Dr. Gerty Cori, the distinguished biochemist who in 1947 shared the Nobel Prize in Medicine and Physiology with her husband, Dr. Carl Cori.

The formal celebration of the anniversary will take place on October 19. To share in this ceremony the President and Fellows of the University have invited representatives from Oxford, Cambridge and Harvard, the universities from which Yale traces its descent, and in addition representatives from the forty-odd American colleges and universities which were originally administered by graduates of Yale. Prof. E. Ll. Woodward, professor of modern history in the University of Oxford, will be the official delegate from Oxford, and Mr. S. C. Roberts, lately vice-chancellor of the University of Cambridge, will represent Cambridge. There are to be formal addresses by Mr. A. Whitney Griswold as President, by Lord Halifax who will be the guest of the University, and by President James B. Conant, the official representative of Harvard University.

There will be a further occasion on Alumni Day, February 22, 1952, when President Griswold and the chairman of the Yale Alumni Board will award Yale Medals to alumni for outstanding service to the University. The anniversary year will come to an end with the Commencement exercises in June 1952. In the future, as during its first two hundred and fifty years, Yale will be mindful of the fundamental purpose of education, phrased by John Davenport as being "for the better trayning upp of youth in this towne, that, through God's blessing they may be fitted for publique service hereafter, either in church or commonweale".

OBITUARY

Prof. Gilbert Cook, F.R.S.

Gilbert Cook, who died on August 28, was born in Blackburn in October 1885 and he received his early education there and in Todmorden, Yorkshire. He distinguished himself at school, and in 1902 proceeded to Owens College, Manchester, where he studied under Osborne Reynolds. In 1905 he graduated in engineering with first-class honours and was awarded a graduate scholarship and the Freebairn Engineering Prize. After spending some time in the engineering workshops and as a pupil of the late D. C. Rattray, chief engineer to the Lancashire and Yorkshire Railway, he was appointed assistant engineer with that company. In 1910 he was awarded a Vulcan research fellowship at the University of Manchester, where J. E. Petavel was director of laboratories, and there he commenced the investigations which formed perhaps his chief scientific interest throughout his life. With Andrew Robertson he published in 1911 a paper on "The Strength of Thick Hollow Cylinders under Internal Pressure" and in 1913 one on "The Transition from the Elastic to the Plastic State in Mild Steel". They were followed by a number of authoritative publications on associated subjects spread over the years.

At the outbreak of war in 1914, Cook was an assistant lecturer in the Engineering Department of the University of Manchester, and he soon laid aside his university duties to serve first in the Royal Garrison Artillery and later in the technical branch of the mining and mine-sweeping service of the Royal Navy. Service routine did not smother his sense of scientific inquiry, and papers on the accuracy of range finders and on submarine depth meters were the outcome of his war-time experience.

Cook returned to his peaceful pursuits in the University of Manchester in 1919, and soon thereafter gained the award of a D.Sc. There followed in 1921 his appointment to the chair of mechanical engineering in King's College, London, where he enhanced his reputation as a teacher and administrator. It was in 1936 that he received the King's commission to be regius professor of civil engineering and mechanics in the University of Glasgow, and there he takes a worthy place in a succession which includes James Thomson and Macquorn Rankine.

Gilbert Cook was a member of the Council of the Institution of Civil Engineers and for many years a member of the Institution of Mechanical Engineers. The election to the fellowship of the Royal Society came to him in 1940. In Scotland he had given valued service to the Institution of Engineers and Shipbuilders, and he was just completing his period of office as president when he died. He served on many educational and technical committees, to which he gave conscientious service. He was consultant and advisor to the Admiralty Hydro-Ballistic Research Establishment, a member of the Advisory Council on Building Research, of the Board of Advisors in Engineering to the University of London and of the Properties and Mechanics of Materials Committee of the Department of Scientific and Industrial Research.

In the fifteen years of his tenure of the chair at Glasgow, Cook made a place for himself in the councils of the University and in the esteem of his colleagues which now cannot readily be filled. He was an excellent teacher, clear and convincing because he was a complete master of his subject. He was a sound administrator because he brought to the consideration of every issue with which he had to deal a logical mind and a conscientious judgment. He was a good colleague, frank, scrupulous, considerate and loyal. In addition to his great qualities of intellect and character, he had a cultured mind and an interest in music. He is survived by his wife.

NEWS and VIEWS

Imperial College of Tropical Agriculture: Prof. A. B. Killick, C.M.G.

The appointment of Mr. A. B. Killick to the Imperial College of Tropical Agriculture, Trinidad, as professor of agriculture, brings to the College a man whose wide experience in tropical agriculture will be of great value to its students. Mr. Killick was a postgraduate student at the College during the academic year 1923–24 and was appointed to the Department of Agriculture, Uganda, in 1924. He served in that Department until 1936, when he was appointed deputy director of agriculture, Trinidad. In 1939 he was promoted to the post of deputy director of agriculture, Tanganyika, and left there in 1942 to become deputy director of agriculture, Kenya. He was appointed director of agriculture, Uganda, in 1947, and is now retiring from that post. In 1950 he was awarded the C.M.G.

Mr. Killick's Colonial experience has covered a wide range of agricultural systems, from the primitive native tribal systems in Tanganyika to the partly mechanized European methods in the Kenya Highlands. In Uganda and Trinidad his work dealt with advanced peasant agriculture, which is approaching the freehold and leasehold farming methods, and he has also gained experience in plantation agriculture—sugar-cane, coffee, pyrethrum, sisal and cacao. He will, therefore, be able to give his students an overall picture of the type of agricultural problems which they will meet when they leave the College in Trinidad for Colonial territories, and they will also have the benefit of his experience in the economics and agriculture of the cotton industry in Uganda, which is now undergoing economic reorganization in view of its financial importance to the Commonwealth as a whole.

Physical Society: Parsons Memorial Lecture

The 1951 Parsons Memorial Lecture will be given under the auspices of the Physical Society by Mr. F. Twyman in the Anatomy Theatre of University College, Gower Street (not in the Science Museum as previously announced), on October 25, at 5.30 p.m. Mr. Twyman will take as his subject "Sir Charles Parsons and Optical Engineering". The Lecture was instituted in memory of Sir Charles Parsons, to be given in turn on the various subjects in which Sir Charles was interested. These included developments in optical instruments and engineering of all types, including naval. The lectures are thus arranged under the auspices of appropriate institutions, the Physical Society undertaking that concerned with optics. Sir Charles Parsons had a deep interest in the making of optical glass of fine quality, and Mr. Twyman has done much arduous and skilful work in improving methods of making high-quality glass and of testing glass and optical components. He was largely instrumental in the development of the Twyman–Green interferometer for the testing of optical flats and prisms for surface flatness and optical homogeneity, and he developed from it the camera-lens and microscope interferometer. In his book "Prism and Lens Making" are many instances of his ability to devise ingenious methods to improve the making and testing of optical parts. A further outstanding achievement was his making of echelon gratings of higher performance than those made by Michelson.

The Effigy of Robert Boyle

The Hon. Robert Boyle, the famous natural philosopher who was one of the founders of the Royal Society, was born at Lismore Castle, in the south of Ireland, on January 25, 1627, and died at his house in Pall Mall, London, on December 30, 1691. His sister, Lady Ranelagh, with whom he had lived, had died a week previously and they were both buried in the chancel of the old church of St. Martin-in-the-Fields, which was replaced in 1721 by the present building. In a letter in *Nature* of October 6, 1921, the late Sir William Tilden gave an account of his unsuccessful efforts to find any memorial to Boyle and concluded that "it seems probable that the last resting-place of the 'Father of Chemistry' will remain unknown to the end of time". Though this appears to be true, there is an effigy of Boyle as a very small boy in "the very famous, sumptuous, glorious tombe" of black marble and alabaster in St. Patrick's Cathedral, Dublin, erected by his father, the great Earl of Cork, in 1631 in memory of his second wife, who had died in 1629 when Robert Boyle was two years old. Richard Boyle, the first Earl of Cork, was born at Canterbury in 1566. After studying law, at the age of twenty-two he went to Ireland, where he held many important posts and became very wealthy. He was made an earl in 1620. His first wife having died in childbirth, in 1603 he married Katherine Fenton, the daughter of Sir Geoffrey Fenton (1530 ?–1608) and his wife Agnes Weston, and by her he had seven daughters and seven sons, of whom Robert was the youngest. The great monument, which now stands at the west end of St. Patrick's Cathedral, Dublin, has four tiers the highest of which has a recumbent figure of Robert Boyle's great-grandfather, Robert Weston (1515 ?–73), the Lord Chancellor of Ireland, and also dean of St. Patrick's. In the next tier are the kneeling figures of Boyle's grandfather and grandmother, Sir Geoffrey Fenton and his wife, while the third tier contains the recumbent figures of the Earl and Countess of Cork, with some of their children kneeling, and the lowest tier of all has representations of the seven younger members of the family, the effigy of Robert Boyle occupying a central arch in this stage. "It is a curious circumstance," says the official work on St. Patrick's, "that it is the only memorial to a man of science in the Cathedral." Though the great Earl is represented in the monument, he died at Youghal and is buried and commemorated in the parish church there. His death took place on September 15, 1643, when his famous son was but sixteen.

Memorial to John Milne

A movement is on foot to create a memorial to John Milne, who is commonly regarded as the 'father of seismology'. Space has been allotted in the Carisbrooke Museum, Isle of Wight, which is a mile from Shide, where Milne did the greater part of his life's work. Any seismological station having any discarded Milne or Milne–Shaw instrument, or parts, used prior to 1914 is invited to communicate with Mr. E. W. Pollard, Cliftonville, Dorking, Surrey.

Aeronautical Engineering Group of Aslib

Approximately a hundred representatives of the aeronautical industry in Great Britain attended a meeting held at the Royal Aircraft Establishment, Farnborough, on September 27 to inaugurate an Aeronautical Engineering Group of Aslib. This is one of a series of specialist groups which are being formed among members of Aslib to consider the recording and dissemination of literature and technical information in special fields. The following committee was elected to control the work of the Group: Mr. R. G. Thorne, Royal Aircraft Establishment (*chairman*); Mr. C. W. Cleverdon, College of Aeronautics (*secretary*); Mr. A. H. Holloway, Technical Information Bureau, Ministry of Supply; Mr. T. G. Dickson, Rolls Royce, Ltd.; Mr. J. A. Kirk, Short Bros. and Harland, Ltd.; Mr. A. R. Cameron, A. V. Roe and Co., Ltd.; Mr. P. S. Walkins, British European Airways; Mr. F. H. Smith, Royal Aeronautical Society; Mrs. M. Neal, *Engineering*. 'Working parties' were set up to consider the following subjects: abstracting services; classification of aerodynamic data; union catalogue of the holdings of aeronautical libraries. Suggestions for consideration by the Group should be sent to the Secretary, Mr. C. W. Cleverdon, at the College of Aeronautics, Cranfield, Beds, or to members of the Committee. It is intended to hold an open meeting next spring to report on the work of the Group.

Meeting of Phycologists at Bangor

A group of twenty-eight phycologists, the majority of them students of marine algæ, met at Bangor, North Wales, during September 13–20. During the week, excursions were made to the shores at Treaddur Bay, Rhoscolyn, Rhosneigr, Penmon Point and the Menai Straits, and one day was devoted to dredging in the Menai Straits, thanks to the kind co-operation of Dr. Crisp and the staff of the Marine Biological Station. These field meetings gave those attending the opportunity of comparing not only the composition of the flora with that of shores more intimately known to them but also the times of occurrence of reproduction of various common seaweeds. In addition, some lesser-known algæ were found and taxonomic difficulties discussed. Prof. P. W. Richards generously provided laboratory facilities, which were used to the full both for the examination of the freshly collected material and also for a series of valuable demonstrations, illustrating the very diverse types of research in progress. Although some of these had bearings on more than one type of problem, these exhibits could be classified broadly as ecological (Blackler, Moss), taxonomical (Burrows and Lodge, Parke, Powell), morphological (Martin, Richards, Mullahy, Dixon), and another group dealt with methods of culture and results obtained by this type of investigation (Parke, Knight Jones, Droop, Drew).

This informal group of phycologists has decided to hold further meetings, thereby hoping to encourage critical and experimental work on marine algæ, and anyone interested is asked to communicate with either Dr. K. M. Drew, Department of Cryptogamic Botany, University of Manchester, or Mr. H. T. Powell, of the Marine Biological Station, Keppel Pier, Millport. A duplicated news-sheet, containing notes of use to marine phycologists, will be available early in 1952, and the preparation of a check-list of the marine flora of the British Isles has been planned. A meeting of about a week's duration has been arranged provisionally to be held at Plymouth during July 1952 when, in addition to field meetings, consideration will be given to a special topic (possibly techniques used in the preparation of material for cytology and in the culture of algæ) and also to the taxonomy of a single family, probably the Delesseriaceæ. Inquiries about the possibility of a one-day meeting in London, during the first week in January 1952, are also being made.

Mythical Dwarf People in Polynesian Legend

The existence of 'little people' is a belief that is of world-wide, though sporadic, occurrence. For the most part, they are dwarfish, more-or-less benevolent, hard-working in spite of their small stature, nocturnal and dwelling underground or in woods or forests. Such being their attributes, they are very difficult to pin down, as their habits make observation extremely difficult, and accounts of them vary with almost every supposed observer. In the Hawaiian Islands these nocturnal pygmies are known as 'Menehune', and Katherine Luomala, whose researches into Polynesian folk-lore are well known, gives an extensive and fascinating investigation of this subject in a booklet entitled "The Menehune of Polynesia and other Mythical Little People of Oceania" (Bernice P. Bishop Museum, Honolulu; Bull. 203; pp. 95; 1951). Her account of these tiny folk is gathered from many sources and includes their physical and cultural characteristics, their housing and social structure, their relations with other little peoples and their possible origin. All this gives them such a corporal existence that it is quite difficult to believe that they are mythical. They originate, apparently, from the old semi-slave common class of people who did all the hard work and were presumably stunted by toil and privation. The buildings they erected seemed worthy of a tradition, and so by the usual process of exaggerating the size of the subjects of the tradition both down and up (the clever little man and the stupid giant) these Menehune became smaller and smaller as time went on in order that their works might be more glorified. Other Polynesian islands also have their legends of Menehune or similar little peoples, and an account is given of the various myths connected with them.

Tarnish and Corrosion of Silver and Bronze

Two papers in the *Museums Journal* discuss the corrosion of silver and bronze respectively, problems which are of interest to a circle far wider than that of museum curators. The article on silver, by Dr. Bengt Thordeman and Mr. Gillis Olson, of the National Historical Museum, Stockholm, is contained in the February issue of the *Journal* and is a summary of their recent investigations of the well-known black or brownish tarnish of this metal. The present solution of the problem is to cover the cleaned silver with a film of nitrocellulose lacquer. The result of this treatment is not completely successful, for in some cases the protecting film gradually cracks and eventually gives rise to a network of unattractive black lines. The authors now consider that the rapidly developing plastics industry has provided a new method of approach, and a commercial lacquer of the acrylate type called 'Acryloid B7', produced by the Resinous Products and Chemical Co., Philadelphia, has been used. The silver is first cleaned by washing in dilute ammonia and removing the resulting film of black sulphide by contact with zinc or aluminium in a weak solution of sodium carbonate. After washing with distilled water and drying at 50–60° C., the still warm objects are dipped in an approximately 8 per cent solution of the lacquer. After excess of fluid has been drained off, the objects are baked at a temperature of 60–70° C. The other article, in the January issue of the *Journal*, is by Mr. J. F. S.

Jacks and is concerned with the cleaning and preservation of bronze statues. He reviews what occurs during the weathering of bronze, and considers the most effective methods to prevent corrosion and to remove the disfiguring products which result when corrosion has taken place. The ultimate colour varies according to the particular impurity present in the atmosphere. For example, oxygen and chlorine give a pale green chloride or oxychloride, while sulphur will produce a dark brown or black sulphide. Also, since impurities in the atmosphere and climatic conditions vary considerably at different times, the resulting patina is often uneven in colour, and a patchy effect is produced. At present it is considered that the application of a thin coating of lanolin forms the best protection from corrosion.

Australian Timbers and Veneers

The demand for plywood in Australia, as in other countries of the world, considerably exceeds the supply; extending production being accentuated by its wider use for housing, internal fitments, prefabrication and innumerable manufactured articles. In a paper entitled "Suitability of Australian Timbers for Veneers" (Bull. No. 260. Commonwealth Scientific and Industrial Research Organization, Melbourne, 1950), Messrs. A. J. Watson and H. G. Higgins summarize the results of investigations, extending over several years, into the suitability of Australian timber species for conversion into veneer, some fifty species having been examined, some systematically, others in a purely exploratory fashion. Certain of the species described are already in common use in plywood manufacture, others in limited quantities only and not for commercial purposes. It is these latter which should prove of importance, since the available supplies of the commonly used species is declining and it becomes necessary to look for new sources of veneer, both from indigenous forests and from plantations. In the case of the former, it has to be borne in mind that not only must the species be suitable, but also that it must be present in the (often mixed) indigenous forest in sufficiently accessible quantities to prove a commercially workable proposition. The data collected in the Division of Forest Products on the subject have been collated in tabular form. Information is given on some relevant characteristics of the trees and wood of the species examined, on their conversion into veneer from the log form, and on the recovery, characteristics and uses of the veneer. The general experimental methods of pre-treatment, conversion and drying are described in conjunction with certain recommendations to industrial operators, emphasis being laid on methods of determining suitable heating schedules for logs before peeling. Supplementary data are given on species recognized as sources of veneer, but which have not been investigated in the laboratory.

Forestry in British Guiana

From the forestry point of view, British Guiana has, perhaps, best been known for its greenheart; otherwise, although it has had a Forestry Department for nearly a quarter of a century, very little progress has been made, nor was much known about forests in the interior. The report of the Forest Department for the year 1949 (Georgetown, British Guiana) states that the previous year was a memorable one in the history of forestry in British Guiana, for it saw the announcement of the Colonial Development Corporation's forestry development proposals in the Colony, and the introduction for the first time of systematic management conditions into new and renewed timber leases. Complete reorganization of the Department was impossible owing to the difficulties in securing senior professional staff. For almost the first time on record in Colonial administration, the Governor himself gave a clear statement of forest policy proposed for the future. He remarked on the heavy capital expenditure needed for the construction of basic extraction facilities and the orderly exploitation of the forest in a series of contiguous blocks based on a predetermined programme. There must be complete control of felling operations in order to prevent undue waste and ensure retention of immature trees for future exploitation, and the retention of seed-bearers to provide natural regeneration; provision must also afterwards be made for improvement operations to ensure optimum growth of economic species. This certainly appears most promising, and an assurance has been given that the Forestry Department will not be overshadowed by the Colonial Development Corporation but that under its present conservator, Mr. C. Swabey, formerly well known in Trinidad, it will hold the reins of progress.

Fisheries Researches in Singapore Straits

One of the chief difficulties confronting fisheries development schemes in undeveloped and under-developed areas—which, incidentally, are mainly tropical—is ignorance. For the proper exploitation of marine fisheries resources, adequate knowledge of the bionomics of the sea areas supporting those fisheries is essential. Such knowledge, for most tropical regions, is extremely meagre or even non-existent, and the appearance of a booklet, "The Food and Feeding Relationships of the Fishes of Singapore Straits", by Tham Ah Kow (Colonial Office Fishery Publication, 1, No. 1; pp. 35; London: H.M. Stationery Office, 1950; 3s. net), is therefore heartily to be welcomed. This publication embodies the results of an intensive study of the inshore fish fauna of Singapore Straits and of the environmental conditions in which it lives. No new tenets have emerged from this work, nor was any to be expected at this stage; but the application of old and well-tried techniques to a new area has produced useful preliminary knowledge of local conditions which can be amplified and supplemented by further researches of a more fundamental type. We look forward to the appearance of further Colonial Office fishery publications dealing similarly and progressively with this and other tropical regions.

Zoological Publications from Victoria University College, New Zealand

The appearance of the first six Zoology Publications from Victoria University College, Wellington, New Zealand, has already been noticed in these columns (see *Nature*, 166, 1098; 1950), and four further papers are now to hand: No. 7, "A Study of the Marine Spiny Crayfish *Jasus halandi* (Milne Edwards)", by C. A. Bradstock (pp. 38, 1950); No. 8, "Keys and Bibliography to the Collembola", by J. T. Salmon (pp. 82, 1951); and No. 9, "Blood Parasites of Mammals in New Zealand", together with No. 10, "A Contribution to the Study of Fijian Hæmatozoa", both by Dr. M. Laird (pp. 14+15, 1951). No. 7 is an account of this very widespread crustacean based on the examination of 2,126 specimens, and it deals with various aspects of their life-history, ecology, population studies, fishery and utilization and includes observations on autotomy and autoplasty; a large female with a carapace-length of 13·5 cm. is estimated to produce 549,000 eggs. No. 8 is a paper that should prove of use to zoologists everywhere. It contains a bibliography which is complete from Delrus and Linnæus (both 1758) up to and including 1949; it comprises 1,216 entries and is a valuable compilation. There is also a key for the whole of the Collembola carried down to genera; and, as the characters given are only those essential for generic identification, the name of each genus is followed by that of its author, the date and a number in brackets referring to the citation of that publication in the bibliography in which the original definition of the genus is to be found. This work is additionally welcome because it provides the first review of the entire order since the memoirs of Borner in 1906 and 1913.

British Contribution to Television: Convention in London

THE Radio Section of the Institution of Electrical Engineers is arranging a convention on "The British Contribution to Television", to be held in London at the Institution during April 28–May 3, 1952. The whole field of television will be covered in nine sessions, each approximately two hours in duration, at which a survey paper and a number of supporting papers will be discussed. First there will be a historical paper and a broad survey paper to act as an introduction to the whole convention, and this will be followed by sessions as follows: programme origination, point-to-point transmission, broadcasting stations, propagation, receiving equipment (two sessions), non-broadcasting applications, and system aspects. In addition to these technical sessions, there will be a number of visits to industrial and other appropriate organizations. Proofs of all papers should be available shortly before the meeting. The convention will be open to all; those who are not members of the Institution will be required to pay a registration fee. The proceedings of the convention will be published in four issues of Part IIIA of the *Proceedings of the Institution of Electrical Engineers*. Further details can be obtained from the Institution of Electrical Engineers, Savoy Place, London, W.C.2.

Colonial Service: Recent Appointments

THE following appointments in the Colonial Service have recently been announced: E. F. Allen and E. J. H. Berwick (agricultural officers, Federation of Malaya), senior agricultural officers, Federation of Malaya; H. Gillman (senior agricultural officer, Tanganyika), deputy director of agriculture, Nyasaland; R. W. Kettlewell (deputy director of agriculture, Nyasaland), director of agriculture, Nyasaland; A. B. Killick (director of agriculture, Uganda), professor of agriculture and director of studies, Imperial College of Tropical Agriculture, Trinidad; A. F. Mackenzie (senior agricultural officer, Sierra Leone), deputy director of agriculture, Sierra Leone; De W. N. Scott (agricultural officer, Federation of Malaya), senior agricultural officer, Federation of Malaya; D. Thornton (senior agricultural officer, Tanganyika), chief soil conservation officer, Tanganyika; A. C. Brooks (chief chemist, Federation of Malaya), director of chemistry, Federation of Malaya; I. A. Beveridge (senior assistant conservator of forests, Gold Coast), conservator of forests, Gold Coast; D. C. Duff (assistant conservator of forests, Gold Coast), senior assistant conservator of forests, Gold Coast; J. M. Cave (assistant agricultural officer, British Honduras), agricultural superintendent, St. Vincent, Windward Islands; C. A. Lea (assistant director, Meteorological Services, Federation of Malaya), director, Meteorological Services, Federation of Malaya; N. A. MacHattie (forester, Tanganyika), superintending forester, Tanganyika; R. H. Ball and P. Bradshaw, agricultural officers, Nigeria; D. V. Chambers, R. Frank, W. G. Mathewson and J. Russell, agricultural officers, Tanganyika; T. J. Forbes and K. Landskroner, agricultural officers, Gold Coast; R. N. Green, agricultural officer, Somaliland Protectorate; G. Heys, agricultural officer, Nyasaland; A. J. Jones, entomologist, Tanganyika; R. Knight, plant breeder, West African Cocoa Research Institute, Gold Coast; C. J. Announcements

WE regret to announce the death on October 6 of Prof. O. F. Meyerhof, For.Mem.R.S., formerly director of the Kaiser Wilhelm Institute of Physiology, Heidelberg, and recently research professor of biochemistry, University of Pennsylvania.

H.M. THE KING OF DENMARK has bestowed upon Dr. D. A. Allan, director of the Royal Scottish Museum, Edinburgh, the decoration of Knight of the Order of the Dannebrog, in recognition of his work in furthering the knowledge of Danish culture in Great Britain and his co-operation with the Danish national museums and kindred institutions.

THE Council of the Illuminating Engineering Society has awarded the Léon Gaster Memorial Premium for 1951 to Mr. H. W. Cumming, of the Research Laboratories of Siemens Electric Lamps and Supplies, Ltd., Preston, for his paper entitled "The Extension of the Gas Arc Condition".

ON the recommendation of Sir Alfred Egerton, director of the Salters' Institute of Industrial Chemistry, the following awards have been made for the year 1951–52: *Salters' Fellowships*: Dr. A. P. C. Cumming and Raymond Grafton; *Salters' Scholarship*: Malcolm McLeman.

THE Sindicato Vertical de Industrias Químicas is holding a conference in Barcelona during November 8–15 on "Safety and Hygiene in Chemical Industry from the Point of View of the Manager, Technician and Operative". Further details can be obtained from the secretary-general of the conference, Sindicato Provincial de Industrias Químicas C.N.S., Via Layetana, 18 Barcelona.

PHYSIOLOGICAL PROBLEMS OF MINING

ON August 9, at the recent meeting of the British Association in Edinburgh, Section I (Physiology) devoted a whole morning session to a number of papers and discussion on "Physiological Problems of Mining". Dr. G. C. Gooding (Scottish Coal Board, Edinburgh), in his review of the "Effects of Lighting on the Health and Working Efficiency of Miners", said that the development of adequate mine lighting in Great Britain has been hindered by the presence of firedamp. The evolution of the miner's lamp has been slow: the electric cap lamp was a big advance, and, although this is the commonest lamp in use to-day, in many districts other less-efficient lamps have not been replaced. Fixed lighting was first used at a shaft bottom in 1881 and is slowly extending. Installations of fluorescent lighting both at the shaft bottom and the coal face have been tried in the past five years and given promising results. Only a fraction of the light produced is reflected from the coal face and this impairs the illumination.

Miner's nystagmus is a disease, which may be incapacitating, associated with inadequate lighting. This disease is now much less common than it was thirty years ago, yet it has disabled for periods of one or more years more than fourteen thousand miners in the decade 1938–47. In some parts, Scotland for example, the disease appears to be checked though not abolished entirely. Continual caution is necessary, since the disease may exist in latent form, which may be converted to overt disability in adverse social circumstances.

With the best lighting available it is now possible to control miner's nystagmus; but good lighting is much more than prophylactic against this disease. Other benefits arising from improvements in lighting in mines are increased output and increased safety. Some small-scale trials have demonstrated both a reduction of accidents and the production of cleaner coal following improvements in lighting. The benefit which is probably the most important is an improvement in physical comfort and psychological temper. An improvement in lighting, sufficient to convert mines into underground factories, would work a revolution in the psychological climate in the industry. Increased comfort is a legitimate aim, being closely associated with industrial efficiency. The miner's job has been described as dirty, dangerous and dark. Attempts have been made, with at least partial success, to mitigate the dirt and reduce the danger. It is a legitimate aspiration for the industry to attempt to remove the dark, and with it another edge of asperity in the miner's life.

The next speaker, Dr. C. M. Fletcher (Medical Research Council Pneumoconiosis Unit, South Wales), discussed the "Effect of Dust Inhalation on the Working Capacity of Miners". Since statistics have been available, coal-miners (and especially elderly miners) have always been shown to suffer from a relatively high mortality from respiratory diseases other than tuberculosis and a relatively low mortality from pulmonary tuberculosis. This relative freedom from tuberculosis was ascribed by J. S. Haldane to a possible beneficial effect of coal-dust. Modern studies have confirmed that the inhalation of coal-dust modifies the effects of pulmonary tuberculosis and that in some ways this may be beneficial. Yet the serious effect of the inhalation of coal-dust on miners' working capacity has become increasingly apparent, especially as the result of admission of miners to compensation under the provision of the Workmen's Compensation Acts for silicosis, in the first place, and now for pneumoconiosis. The prevalence of pneumoconiosis has been very much greater in South Wales than in the other coal-fields, and the reason for this is not certain.

Pathological studies have shown that dust accumulates in and around the bronchioles where there is a minimal reticulin reaction to its presence. At this stage, simple pneumoconiosis, the dust could not be expected to cause any important disturbance of respiratory function. In elderly coal-workers the lung tissue in the neighbourhood of the deposit of coal-dust may become broken down to form 'focal emphysema'. If there are no complications, this focal emphysema is only occasionally so severe as to interfere with respiratory function. In some cases of coal-worker's pneumoconiosis, collagenous fibrosis occurs in the deposits of coal dust. Collagenous nodules of irregular shape form and later coalesce to form large areas of massive fibrosis which may seriously distort the lung and interfere seriously with its function, and in addition impose a strain on the pulmonary circulation.

Radiological studies enable a distinction to be made in life between simple pneumoconiosis and massive fibrosis, and a system of radiological classification has been developed. A correlation has been worked out between the radiological findings and a test of respiratory efficiency, and from this it is concluded that serious disability in coal-worker's pneumoconiosis is chiefly due to the presence of massive fibrosis.

"Coalminer's Pneumoconiosis: Employment Problems of the Disabled" was the subject of a paper by Dr. A. Meiklejohn (University of Glasgow). While hitherto the main incidence of certified pneumoconiosis has been in South Wales, there is evidence that, for various reasons, the number is increasing in other mining areas. It is not possible to provide satisfactory alternative jobs for these disabled miners. Reluctantly the conclusion has been reached that almost the entire responsibility for the continued employment of pneumoconiotic coal-miners must be accepted by and within the industry. The problem is not rehabilitation of disabled coal-miners, but rehabilitation of unfit coal-mines. In this assignment the main burden must fall on the employers and mining engineers, not on doctors and sociologists. There can be no speedy amelioration without the vital co-operation of the men themselves and their unions. This constitutes a challenge to discipline and leadership.

There are several important prerequisites which must be fulfilled. First, the whole problem must be extracted from 'politics'; secondly, it must be realized that pneumoconiosis of coal-miners is not peculiar to South Wales; thirdly, the fine focus on disease and compensation must give way to the acceptance that existent knowledge of the causation of the disease is already adequate, without further research, to enable effective prevention. Mining engineers in South Wales, by such methods as water infusion, have already made a useful start. The clamant demand is for more coal—higher and greater production. To this end mechanization and more mechanization and more men to work the machine is the invariable answer. Is it quite certain that in some mines more coal-cutters and longer conveyor-belts are not indirectly diminishing output by the deleterious effects on the men ? It has almost become trite among doctors to say this is an engineering problem. Until the disease is controlled so as not to abridge life or seriously impair health in a normal working span, then the medical man must bear his full part in the team. But in this particular field the medical man is simply an expert adviser ; he is not the director in charge of operations. Though the production of dust must be kept to a minimum, considerable dust is unavoidable, and the occurrence and, in certain circumstances, the progression of the disease reflects the extent of the dangerous concentrations of air-borne dust. The medical man has two main duties : first, to assist the engineers to locate the dangerous operations and stations, and secondly, to supervise the health of affected men still at work.

The final speaker, Sir Andrew Bryan (National Coal Board, London), speaking on "Accidents in Coal Mines", said that of all the major industries in Great Britain, coal-mining is the most hazardous. Employing less than one-twentieth of the working population, it accounts for nearly one-quarter of all industrial accidents. The reasons for this high accident-rate lie in the nature of the work of the miner and in the vital differences between his working environment and that of other industrial workers. Mining is for the most part a continual striving against great natural hazards in confined and poorly illuminated spaces.

Up to the present time the attack upon the accident problem has been mainly by statutory regulation and inspection, assisted by scientific research into specific mining dangers and a raising of the standards of education and training of miners ; and, more directly, by improvements in standards of housing, welfare and recreational facilities for the mining community as a whole. That these lines of attack have achieved a considerable measure of success over the years is shown by the progressive reduction in the accident-rates for fatal and serious non-fatal accidents. There is still much to be done along these lines. The attack must continue by way of further regulations as the results of new mining methods, machines and safety practices are devised ; by way of higher standards of education or training for mine managers, officials and workmen; by the general adoption of higher standards of engineering production; and by the expansion of social and welfare activities in all mining communities. But new methods are needed if the progress of accident reduction is to be accelerated ; and for this purpose new methods of investigation are required.

As examples of new lines of approach, the relationship between accident-rate, absenteeism and size of pit has been considered. There is a close correlation with the size of pit and the accident-rate per 100,000 man-shifts. In pits employing less than fifty miners the rate is 63·5, but rises to 166·6 in pits with more than three thousand. The reasons for this require study. Further, it can be shown that a high accident-rate can be correlated with a high pneumoconiosis-rate. Researches into observable features of human behaviour such as accident-rates, and their relation to the size of the groups in which men work, may, in the final result, throw light upon the structure of authority in the pit and the extent to which the men feel themselves to be part of the organization in which they are employed. Coal must always be got by small groups of men working in isolation and under remote supervision. The attitudes of these groups and the extent to which they each identify themselves with the pit as a whole are problems needing urgent investigation that confront the industry.

SENSES AND BEHAVIOUR OF ANIMALS

ON August 13 at Edinburgh the second joint session of Sections D (Zoology) and J (Psychology) of the British Association (the first was at Aberdeen in 1934) was held under the chairmanship of Dr. C. F. A. Pantin, the subject being the "Senses and Behaviour of Animals".

Prof. R. J. Pumphrey (University of Liverpool) spoke of the coming of age of 'ethology', a word recently applied to the study of the behaviour of all animals including man. Ethology, in this wide sense, evidently stems from the "Origin of Species" (1859) and the "Expression of the Emotions in Man and Animals" (1872) ; but its development has been arrested until very recently. This arrest is traceable to the influence of Descartes. In spite of the intellectual acceptance of evolution as a fact of history, a conscious or sub-conscious reservation in favour of dualism led to the persistent separation of a human ethology (psychology) which was rootless and arid, from an animal ethology, which carried the worship of the Golden Calf of objectivity to ludicrous lengths. The many 'languages of objective description' that have been applied to animal behaviour are seen in retrospect to cloak a belief in a physico-chemical etiology of behaviour, and an equation of meaning with statistical significance.

Prof. Pumphrey concluded that the time is now ripe for an integrated ethology with a common language and a common aim. A re-examination of the basic principles of semantics is needed, for semantics is doubly involved in ethology, both in the technique and in the description and interpretation of results.

The next speaker, Prof. J. E. Harris (University of Bristol), pointed out that a physiological and 'mechanistic' treatment is still appropriate to the genesis of behaviour patterns in the embryo. He showed in detail how this genesis can be related to the development of the muscular and nervous systems of young fish and amphibians, and how the first myogenic movements and rhythms are modified as motor and sensory nerve cells, and connexions and tracts become functional until the swimming rhythm is perfected.

Prof. R. W. Russell (University College, London) said that he was a psychologist and necessarily approached animal ethology with the terminology and point of view of human psychology. Nevertheless, he agreed with Prof. Pumphrey about the importance of semantics and the desirability of an integrated ethology with a common language. Such meetings as the present joint discussion and the Cambridge symposium on behaviour two years earlier reflect the desire of psychologists and animal ethologists alike to understand each other and to contribute jointly to an understanding of behaviour.

Prof. Russell then described the extensive field of animal psychopathology which has been explored since the first studies in experimental neurosis in Pavlov's laboratory at the beginning of the century; and he convincingly demonstrated the close resemblance in the symptoms of neurotic behaviour of man and animals and in the situations which produce it. There is a fundamental difficulty in distinguishing 'normal' and 'abnormal' behaviour of animals in laboratory situations which are *ex hypothesi* abnormal. Nevertheless there is a promise, if not more than a promise, that animal and human psychopathology can be unified with significant results for our understanding of human behaviour.

In a review of learning by animals other than man, Dr. F. H. George (University of Bristol) emphasized the extent to which, after the earlier pioneering of Lloyd Morgan and Pavlov, the world was indebted to the United States for investigation in this field and for the elaboration of its somewhat indigestible theory. He emphasized in particular the unsatisfactory theoretical position of 'punishment', Muenzinger *et al.* and Drew having shown that 'punishment' is as effective in reinforcing a right choice as in correcting a wrong one. He outlined the conflicting theories of learning of Tolman and Hull and seemed at least to hint that the conflict is partly verbal and terminological. Like previous speakers, Dr. George stressed the importance of a new semantic approach to ethological problems and suggested that a really comparative attitude is likely to be productive. In the 'comparative' psychology of recent years, 70 per cent of published papers deal only with the Norway rat.

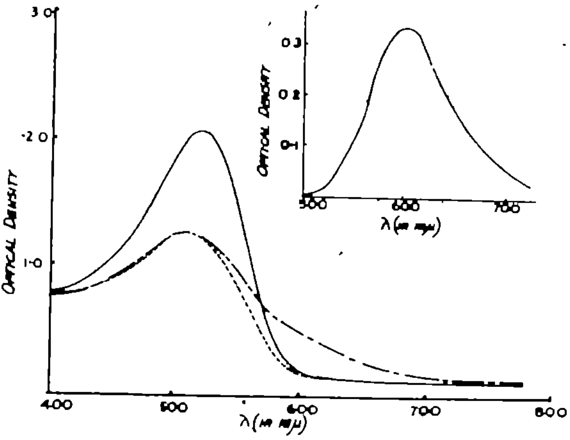
In the subsequent discussion, Prof. H. R. Hewer neatly pointed Dr. George's concluding remarks, and criticized by implication the abstractness and remoteness from reality of much modern work on learning and behaviour. During the Second World War he had been concerned with others in countering the depredations of wild rats. Search of the enormous literature on the behaviour of rats in laboratories had disclosed little that was relevant or useful in the control of wild rats. It was not at that time even known how they ate.

EFFECTS OF X-RAYS UPON PLASTICS

Electronic Processes

IN continuation of our work on systems suitable for the dosimetry of ionizing radiations, and in particular the measurement of three-dimensional dose distributions[1], we have experimented with some coloured plastics. The observed phenomena, while indicating some applicability to the measurement of radiation, have aspects of more general interest.

It was found that of a series of thirty-two samples of commercially available polymethylmethacrylate ('Perspex'), coloured with various materials, three samples showed an appreciable change of colour when irradiated with X-rays. Similar results could be obtained using a plastic prepared by polymerization of an acrylic monomer coloured with benzene-azo-benzene-azo-β-naphthol (Sudan III). These colour changes are more intense than the slight colour changes shown by uncoloured 'Perspex', and of a different spectral composition. In addition, they are completely different from the slight bleaching caused in the same materials by ultra-violet light. The X-ray effect consisted in each case of the development of an absorption band at a wave-length longer than the absorption band of the basic dye, and manifested itself visually in a darkening of the colour. At the same time the optical density in the original absorption band of the dye decreased (see diagram).



Absorption spectrum of 'Perspex Red 400'
Curve 1, —— before irradiation; curve 2, —·— immediately after irradiation; curve 3, ---- 6 days after curve 2, in the presence of oxygen (complete penetration). Inset: Absorption band produced by the radiation (difference of curves 2 and 3)

The optical density in the new band produced by a given dose of radiation increases with the concentration of the dye in the plastic, and is also dependent on the concentration of oxygen. In the absence of oxygen the change in absorption coefficient is proportional to the dose (approximately 0·02 per cm. per 1,000 r. in 'Perspex Red 400'), whereas in the presence of dissolved oxygen in equilibrium with 1 atm. of the gas, scarcely any change occurs for the first 10^6 roentgens, and the rate of change increases at higher doses to approximately the same value as obtained in the absence of oxygen. If, after irradiation, oxygen is permitted to diffuse into the plastic, a partial reversal of the phenomenon occurs, so that the new absorption band due to the irradiation disappears; but the absorption at the original peak does not return to its normal value. A thermal back-reaction is also observed, which is very slow at room temperature, taking several months for completion.

These results are interpreted as showing that some of the electrons liberated from the lattice by radiation become trapped by and attached to the dye, the proportion depending on competition for the available electrons between the dye and other acceptors in the lattice. As a result of the irradiation, a system of positive holes and negative ions is formed. The phenomenon is analogous to the production of colour centres in alkali halide crystals. The system would not normally be chemically stable, but is evidently 'frozen' into the plastic lattice, and decomposes or recombines only very slowly at room temperature. This is a noteworthy difference from, for example, aqueous solutions, where the primary processes are presumably identical, but are followed much more readily by secondary chemical reactions.

Oxygen evidently competes for the electrons, forming O_2^-, and owing to its greater electron affinity is capable also of effecting an electron transfer from the dye:

$$\text{Dye}^- + O_2 \rightarrow (\text{dye} \ldots O_2^-),$$

where electron transfer has occurred, but the two species may be held together by the residual electron affinity of the dye.

The odd ions formed in these processes should exhibit paramagnetic resonance, and this has been found to be the case[2]. These coloured plastics are therefore solid systems, in which one has some control over the nature and number of the electron trapping sites. At the same time, the velocity of the thermal back-reaction is sufficiently small to permit accurate observation. The effect may be related to the increased conductivity[3] and fluorescence of plastics under irradiation[4] previously reported. It seems, therefore, that these systems might yield useful information on electron capture processes in solids. Further experiments on the chemical and physical aspects are in progress.

We wish to thank Imperial Chemical Industries, Ltd. (Plastics Division), for specimens of 'Perspex', Mr. W. A. Jennings for valuable comments, and Dr. F. T. Farmer and Dr. Joseph Weiss for their interest and support.

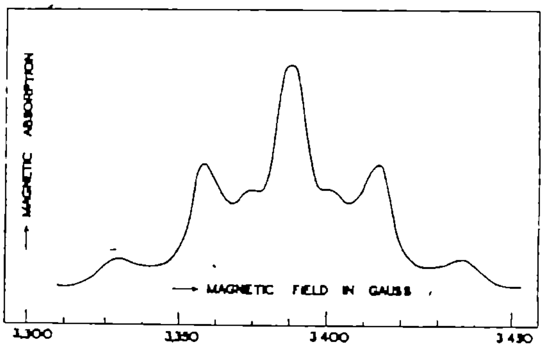
Paramagnetic Resonance

Using the sensitive micro-wave apparatus described recently[1], operating at 9,500 Mc./sec., sharp paramagnetic resonance spectra have been obtained with a number of plastics after irradiation in a 200-kV. X-ray therapy set. The main experiments have been carried out with specimens (2 cm. diameter × 0·3 cm.) of coloured polymethylmethacrylate ('Perspex')[2] and of clear uncoloured 'Perspex'. The observed intensities and widths of the resonance absorptions and their increase with X-ray dosage, which was varied between 10^6 and 10^7 roentgens, are in accordance with the assumption that the magnetic centres are electrons produced as the result of irradiation and trapped in the plastic lattice.

The structure of the resonance is the same for both types of specimen, consisting of a central peak symmetrically surrounded by a number of satellites (see graph). There is, however, a marked difference between the coloured and clear 'Perspex' in the position of the resonance spectra, providing evidence of differences in the nature of the trapping sites. In the coloured specimens the centre of the resonance lies at a magnetic field corresponding to a g-factor within 0·1 per cent of the free spin value, whereas in the clear 'Perspex' the resonance pattern is shifted down-field by some 20 gauss ($g = 2·014$), indicating interaction of the trapped electrons with surrounding atoms. The symmetry of the resonance pattern of the dyed 'Perspex', in which no trace of the displaced clear 'Perspex' lines is detectable, suggests further that the presence of the dye molecules provides electron traps which are considerably deeper than those in the plastic host lattice. Other results point to the same conclusion, such as the stability of the trapped electrons in the dyed as compared with the undyed specimens shown by resonance experiments at long periods after irradiation, and the less severe competing effect of oxygen demonstrated by resonance observations at small X-ray doses with specimens of varying oxygen content. It should be noted that the electrons captured by oxygen molecules, and the positive holes, that is, the sites in the plastic lattice which have lost electrons during irradiation and consequently have unpaired electron spins, are assumed to produce no resonance effects detectable with the present apparatus. With this qualification the resonance experiments have gone far in supporting the arguments on the effects of X-rays on plastics presented in the preceding communication as the result of optical measurements.



Magnetic resonance spectrum of irradiated 'Perspex'

The remarkable fine structure of the paramagnetic resonance of the observed resonance spectra is of even more general interest, since it appears to reflect characteristic properties of the structure of plastics. In the 'Perspex' resonances obtained at small X-ray dosage, lines are detectable at ± 12 and ± 46 gauss from the centre, besides the main satellites at ± 25 gauss. Resonances having a similar pattern have been observed with irradiated polystyrene; here the main satellites are at ± 18 gauss. It is believed that the satellite resonances are caused by regularities in the spacing in the plastic lattice of the trapping sites for the magnetic units (electrons and possibly positive holes). Magnetic dipole interaction between neighbouring spins would thus lead to a non-random distribution of the internal magnetic field acting on the resonating electron spins. Considering only the effect of nearest neighbours and neglecting the statistics of their spatial distribution, a crude estimate of a characteristic minimum separation r_0 between adjacent spins can be obtained by identifying the field separation of the main satellites from the resonance centre with the internal field μ_e/r_0^3 produced by a single adjacent spin. The values for r_0 of 17 A. and 19 A. derived from the observed resonance spectra for polymethylmethacrylate and polystyrene respectively may be related to one of the regular 'identity periods' derived for the specific plastics from X-ray diffraction measurements[3].

A METHOD FOR MAKING ULTRA-THIN TISSUE SECTIONS FOR ELECTRON MICROSCOPY AT HIGH RESOLUTION

By FRITIOF SJÖSTRAND
Department of Anatomy, Karolinska Institutet, Stockholm

DURING recent years, some techniques for making tissue sections for electron microscopy have been worked out which make it possible to prepare sections about 0·2 μ thick[1-7]. The resolving power of the electron microscope at this specimen thickness is estimated as 100–200 A., being different in different structures of the tissue cells because of differences in electron scattering power of the structures.

There seems to be a definite limitation of the techniques tried, due to compression and breaking of the sections when cut. In order to make use of the whole resolving power of modern electron microscopes, the thickness of the sections has to be only a few hundred angstroms or less. The demands regarding the thickness are determined by the size of the structural elements to be studied.

In order to obtain sufficiently thin sections for electron microscopy at high resolution, a technique has been worked out, the principle and first trials of which were published in 1943 [8-10]. The idea was to prepare sections without interference of the limiting factors mentioned above. This is possible by the use of a double sectioning technique. First of all, sections 0·5–1 μ thick of double-embedded (collodion–paraffin) material are cut on a Spencer microtome (No. 821) using the technique of Hillier and Gettner. Ribbons of serial sections are re-embedded in collodion on the accurately plane surface of a piece of glass. The surfaces of this glass are made to meet the same criterion for parallelness as are fulfilled by the well-known Johansson gauges, and in addition they are optically polished.

This glass 'measure' is placed in a specially constructed microtome on the plane upper surface of the advance mechanism, where it is kept in place simply through the cohesion between the plane surfaces in contact. A specially sharpened razor blade is used as knife, the edge of which travels parallel to the upper surface of the advance mechanism. The deviation from a parallel advance is 50–100 A. per mm. advance.

With this knife a greater part of the embedded sections is cut away and discarded, and the remaining part is mounted for examination in the electron microscope. This remaining part can be made extremely thin, as it has not been deformed during sectioning. The principle of cutting is illustrated in Fig. 1.

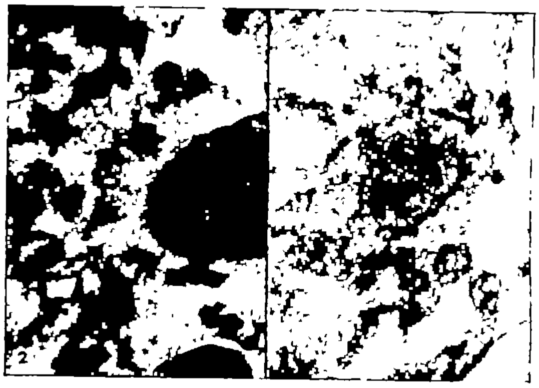

Fig. 2. Thicker region (about 0 2 μ thick) of section from mouse liver, fixed in 2 per cent osmic acid for 24 hr. 5,000 ×
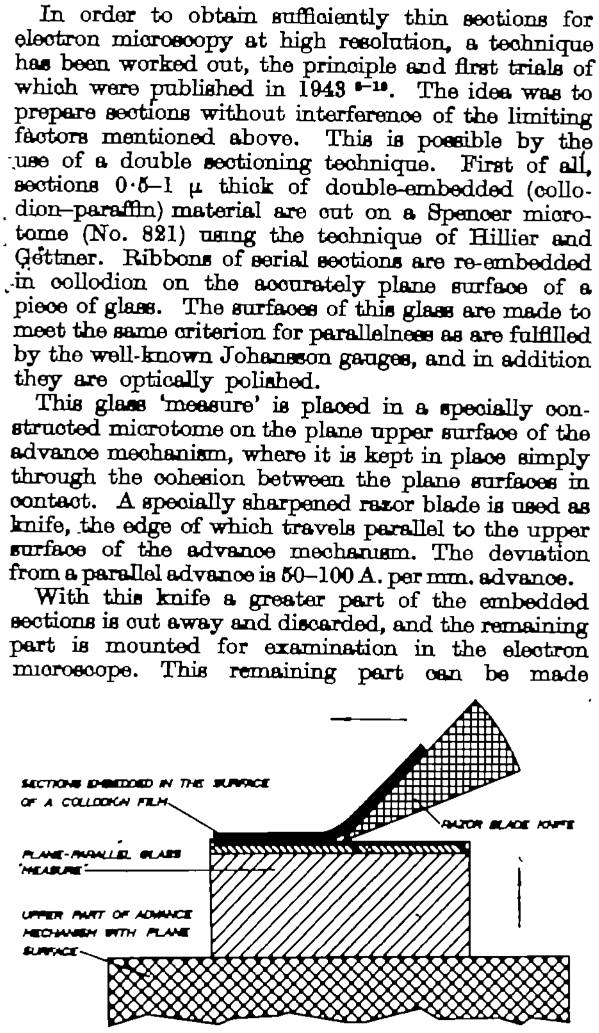
Fig. 3. Adjacent thin region from the same section. In this picture the contrast has been much enhanced during photographic printing. 5,000 ×



SECTIONS EMBEDDED IN THE SURFACE OF A COLLODION FILM
RAZOR BLADE KNIFE
PLANE-PARALLEL GLASS 'MEASURE'
UPPER PART OF ADVANCE MECHANISM WITH PLANE SURFACE

Fig. 1. Principle of the double sectioning technique

In order to control the thickness of the sections, the thickness of the original sections has to be known and must not vary too much. The advance mechanism also must allow a very precise and accurate movement relative to the knife-edge. This movement is directly registered in angstrom units with an accuracy of better than 250 A.

The chances for getting sections of the right thickness are increased with experience of the processes of embedding and sectioning. From each ribbon of sections mounted on one glass 'measure' several sufficiently thin sections are obtained to allow the use of this technique as a routine method for the study of a large number of sections without an unreasonable expenditure of time.

For the analysis of the sections, an RCA *EMU 2 c* electron microscope with compensated standard objective pole-piece and the standard objective aperture was used. The pictures have been obtained with minimal electron bombardment. Fig. 2 shows a thick part of a section through a mouse liver. The thickness of this part of the section is estimated to be about 0·2 μ, judged from experience regarding the electron scattering of that kind of sections.

Fig. 3 shows an adjacent thin part of the same section, with the contrast highly accentuated during the photographic printing. The most characteristic feature of the thin sections is the very low scattering power, with a decrease of contrast differentiation of the larger structural elements of the cell when compared to the thick sections. On the other hand, the resolution is much improved and makes it possible to explore the ultra-structure of the cell organelles.

Fig. 4 shows a part of a section through the nerve myelin sheath from the sciatic nerve of a guinea pig at a magnification of 135,000. Periodic striations, the period of which is 50–80 A., are visible, presumably corresponding to a concentric arrangement of the membranes observed on fragmented nerve[11-13]. Indications of such a periodic structure in sections were first noticed by H. Fernandez-Moran[13].

The tissues were fixed in 2 per cent osmic acid (24 hr.). The conditions of fixation are critical when ultra-thin sections of this kind are prepared. The artefacts introduced through the fixation, embedding and sectioning will be systematically studied.

Fig. 4. Section through myelin sheath from guinea pig sciatic nerve, fixed in 2 per cent osmic acid for 24 hr. 185,000 ×

It is impossible to measure the thickness of these sections; but judging from the contrast of the sections as compared to the contrast of the supporting film when doubled at folds and ruptures, the thickness of the thinnest parts of the sections is estimated to be of the same order of magnitude as the supporting films ordinarily used, or a few hundred angstroms.

A more detailed description of the technique will be published elsewhere. [May 15.

RESEARCH DEPARTMENT OF THE BRITISH BROADCASTING CORPORATION

NEW SITE AT BANSTEAD

IN the early days of broadcasting in Great Britain, the British Broadcasting Corporation soon found itself faced with a variety of technical problems which could not be resolved by the engineering maintenance and operating staff. A Research Department was formed in 1929, and five years later this section of the Corporation was housed at Nightingale Square, Balham. When, after the War, the normal work of the Department was resumed, it became clear that larger premises were necessary to deal with an enhanced programme of research. A suitable building, standing in twenty-seven acres of ground, was found at Kingswood Warren, Banstead, some twenty miles south of London. The mansion itself has been adapted to the needs of the Research Department staff with laboratories, offices and restaurant facilities. In addition, there is ample space for outdoor experimental work, as well as for the erection of two new laboratory blocks, one of which has been completed.

An 'open day' at this new site of the Corporation's Research Department was held on June 20, at which a number of exhibits and demonstrations were available for inspection to illustrate the work of the Department. On this occasion, also, an illustrated brochure, entitled "BBC Research Department, Engineering Division, 1951", was issued. This publication shows that the Department is organized into four Sections at Kingswood Warren, in addition to the Electro-Acoustics Group, which is still housed at Nightingale Square.

Among the most interesting activities at the present time is that of the Television Section, which deals with investigations into the electrical and optical performance of camera tubes as developed by the radio industry, and with the properties of the various circuits used in television technique. In addition, work is directed to an appraisal of the various problems involved in colour television, including its fundamental physiological aspects. The recording of television programmes on film is an item of investigation about to be undertaken.

The very limited number of frequency channels available for sound broadcasting has made it necessary for some time past for the Field-Strength Section of the Department to study the propagation of radio waves within the service area of each transmitting station. This work has recently been extended from medium frequencies to those involved in television and very-high-frequency sound broadcasting. Closely associated with this is the work of the Aerial and Transmitter Section, which is concerned with the development of aerial systems designed to give the largest local-service area of coverage or, in international broadcasting, to direct the programmes to the zone or country in which reception is desired. The Receiver and Measurements Section keeps abreast of developments in the design of broadcasting receivers and carries out tests on typical commercial products. It also designs receivers for special purposes, such as, for example, the standard receivers being used in tests on the relative merits of amplitude- and frequency-modulation in transmissions at very high frequencies.

At Nightingale Square, the Acoustics Section is responsible for experimental work connected with the design of studios and the basic principles of reverberation. Techniques have been developed in which the response of a studio to transient sounds is displayed on a cathode-ray oscillograph. A new method, not so far used elsewhere, makes use of a pulsed gliding tone, in which the frequency of the tone is gradually increased, and the changing form of the oscillograph display is photographed on slowly moving film. In the Recording Section, a thorough investigation of the disk-recording process has led to the design and construction of a disk-recording machine, since no equipment available commercially provides all the facilities required while meeting the standard of fidelity considered essential. Investigations in magnetic recording now absorb the major part of the Section's effort.

To assist in all this work, the Research Department has built up its own model shop, which is fully equipped to undertake the construction of the majority of the apparatus required; this is of a varied nature and may be of mechanical, electrical or optical type. As a normal part of its activities the Department maintains close touch with other broadcasting authorities, with research organizations and with industry. Finally, great importance is attached to the publication of the results of research work; and the staff are encouraged to prepare papers for reading before scientific societies, or for publication in scientific and technical journals and in the *BBC Quarterly*.

NUFFIELD FOUNDATION

ANNUAL REPORT

THE outstanding feature of the sixth report of the Nuffield Foundation*, covering the year ended March 31, 1951, is the passage in which is considered the prospect of some curtailment of scientific research through rising costs, and whether the resources of such charitable trusts as the Nuffield Foundation should be used for sustaining academic activities thus endangered or for encouraging novel projects which may find it even more difficult to secure support. The present report indicates that, for the remaining three years of its present programme, the Foundation will continue to give preferential support to fundamental biological and social studies. This policy is succeeding, but its other main preference for the period—the encouragement of specialists in various fields to apply their knowledge and techniques to the study and solution of practical contemporary problems—has not attracted the same support. In addition, the Foundation continues to assist research of exceptional merit in any branch of science, and its schemes of training fellowships and travel grants are being expanded, and from the year's income of more than £550,000, some £55,250 was allocated for new or continuing schemes of this type, with a further £88,000 to be met from succeeding years. Of new grants totalling £386,194, £20,950 was used from the Oliver Bird Fund and other resources for research in rheumatism, £46,640 for fundamental biological and £111,000 for sociological research in the United Kingdom and £71,500 for research overseas within the Commonwealth. The original contribution of £500,000 to the National Corporation for the Care of Old People is not yet exhausted, and medical research on ageing is still similarly financed from an earlier allocation; no new grants have been necessary. As provision for a new headquarters when the Foundation is required to vacate its present premises, £135,000 has been set aside this year.

In continuation of its past programme the Foundation has increased by £3,650 the grant to the University of Bristol for Dr. C. R. Burch's work on the development of the reflecting microscope. Patents covering the present processes of manufacture offered to the Foundation are being put before the National Research Development Corporation for development in the national interest. In the medical sciences, the Foundation has made a grant of £750 for an additional full-time worker for epidemiological and bacteriological studies in the 'thousand-family' investigation being conducted by the Department of Child Health, University of Durham. In the social sciences, the Foundation is continuing its aid to Political and Economic Planning on the diminishing scale of £4,500 over the years 1951–53, while an additional grant of £1,000 has been made to the Caldecott Community to enable the children's reception centre to follow up the children who have passed through the centre or been 'placed' on its advice.

A gift of 1 kgm. of cortisone was made by Merck and Co., Inc., jointly to the Medical Research Council and the Foundation, and a new joint committee was set up to examine projects of clinical trial and research and allocate supplies both of cortisone and adrenotropic hormone. A three-year grant totalling £5,000 has been made to the Department of Human Ecology at the University of Cambridge for a medico-social survey of the Fen district of East Anglia covering the types and prevalence of rheumatic disease. A grant of £4,000 has been made to the Department of Chemistry, University of Birmingham, for the study of tendons, cartilage and tissue components and their structural chemistry, and £1,000 to the Medical School, University of Leeds, for special equipment for chromatographic techniques in the study of pathological collagen, while a grant of £1,050 a year for two years has been made for the appointment of a senior and a junior research fellow to work under Dr. D. M. R. Barton at Birkbeck College, London, on the synthesis of cortisone by the ergosterol route. The grant to the rheumatic unit at the Department of Medicine, University of Edinburgh, has been increased to £2,364, and that to Mr. A. Law, of the Orthopædic and Accident Department, London Hospital, for perfecting techniques of reconstructive surgery in chronic arthritis of the hips and spines, was renewed, as well as that to the South-West and Oxford Regional Research Unit, Bath.

New grants for fundamental research include £5,340 over five years, for a research assistant and technician under Prof. F. G. Young at the School of Biochemistry, University of Cambridge, for the perfection and running of the mass-spectrograph, and £1,000 a year for five years to the Physiological Laboratory at the same University for equipment and materials for workers under Prof. E. D. Adrian. A five-year grant totalling £20,000 has been made to Prof. C. Rimington, of the Department of Chemical Pathology, University College Hospital Medical School, London, for a small unit to continue and develop his investigations on the chemistry and biochemistry of hæm and other pyrrole pigments, and a grant of £500 for equipment and £400 a year for two years for a technical assistant has been made to Dr. E. Wangermann to enable her to continue at University College, Leicester, the work initiated under Prof. E. Ashby at Manchester on growth-rates of populations of common duckweed (*Lemna minor*) under controlled conditions. A further grant of £1,000 a year for five years has been made for an additional research worker to collaborate with Dr. C. Causey in work on certain aspects of nerve-cell body and axon as part of the work under Prof. J. Z. Young on the physiology of learning at the Department of Anatomy, University College, London, in which Mr. F. Roberts has now devised and built a 'flying-spot' microscope which has novel possibilities both for magnification and for counting and measuring particles of living tissues. A grant of £10,000 over the next five years has been made to the Department of Zoology and Comparative Anatomy, University of Oxford, for research under Dr. E. B. Ford on the evolutionary genetics of wild populations.

In the sociological field, the Foundation has offered a grant of £2,000 to the University of Birmingham to complete, under Prof. Charles Madge, the survey of a Midland market-town commenced in the Department of Social Science, and one of £4,000 to the Department of Social Studies, University of Leeds, for a two-year project to examine the changing relationships between the family and the community in an industrial village within easy reach of Leeds. The Foundation is also providing £3,750 for a survey by the Department of Social Science, University of Liverpool, of social relations in the dock-working community; under the general direction of Prof. T. S. Simey, this survey is intended to cover the relations between individuals and social groups which develop informally and spontaneously at work-level; between the subordinate and his immediate superior; and between individuals and social groups and officials and institutions with which they are brought into contact. An additional grant of £1,250 has been made to the London School of Economics and Political Science for the establishment of a Division of Research Techniques, and £100,000 over ten years for two additional fellowships, to be called Nuffield readerships, at Nuffield College.

---

* Nuffield Foundation. Report for the Year ending 31 March 1951. Pp. 113. (London: Nuffield Foundation, 1951.)

New grants for research overseas include £900 a year for two years for a research fellowship for Dr. F. Douglas Stephens at the Children's Hospital, Melbourne, for research on problems of child surgery; up to £3,500 to the University of Melbourne, for appointment of a medical biochemist for two or three years in the Department of Biochemistry; £1,500 for special equipment for neuro-anatomical research in the Department of Anatomy, Histology and Embryology at the Christian Medical College, Vellore, and £300 a year for two years for a programme of meteor research at the Department of Physics, Canterbury University College, New Zealand.

The Foundation is also providing up to £12,000 for a review, jointly sponsored with the Secretary of State, of the policy and practice of education in the Colonial territories in Africa. The group investigating methods of work measurement used by industry in Great Britain is beginning inquiries as to why progressive managements continue to use time-study practitioners; what it is that management values, and why, in the existing methods; and what information industry would like to get from such techniques that existing methods do not supply. Fundamental scientific research into the measurement of human performance on skilled operations is also being initiated.

New fellowship and scholarship schemes during the year include a small number of biological scholarships and bursaries for graduates of the United Kingdom normally resident there, and sociological scholarships and bursaries for special training in sociological subjects, and a visiting studentship for a South African physiologist. Four United Kingdom medical fellowships were awarded; but there was even less response than in 1949 to the Foundation's offer of dental fellowships and scholarships. A final award of six fellowships, four postgraduate scholarships and ten vacation scholarships brought the total awards under the scheme for the advancement of extraction metallurgy to 23 fellowships, 21 postgraduate and 49 vacation scholarships. The scheme for travelling scholarships for young farmers is now extended to the whole United Kingdom. Only one travelling fellowship for the Home Civil Service was awarded in 1951; but India, Pakistan and Ceylon have now accepted the Foundation's offer of five, three and one fellowships respectively for study in Great Britain. Two further travelling scholarships were awarded to farmers of Southern Rhodesia for 1951.

For research into ageing, the Foundation has made a grant of £1,000 a year for two years to Dr. Alex. Comfort to work in the Department of Zoology, University of Birmingham, with a capital grant of £650 for apparatus and recurrent grants of £200 to the University for the costs of research. A grant of £2,600 over two years has been accepted by the University of Oxford for an examination, in the Nuffield Department of Surgery, of the changes in the blood-vessels of the brain as a result of ageing. An offer of £1,250 a year for a three-year trial period has been accepted by the Australian Committee of Vice-Chancellors for a full-time secretariat. A grant of £1,300 a year for three years has been made to the Scientific Department of the National Gallery to assist an examination, by the reaction to low-voltage soft X-rays, of the characteristics of organic materials, particularly synthetic resins, with the aim of discovering what can be learnt about condition and about picture structure as such, and also an examination of the swelling and solvent action of organic solvents on natural and synthetic varnishes and pigmented linoxyn films. A grant of £4,000 has been made to the Royal Institution towards the cost of reconstructing and re-equipping a modern workshop in the Davy Faraday Research Laboratory.

CHILDREN'S LEISURE

THE findings of a survey, carried out by the Social Survey Division of the Central Office of Information, into the out-of-school interests and activities of school children has recently been published*.

Information was obtained from the parents—chiefly mothers—of about 1,600 children, forming a representative sample of school-age children of England and Wales, and also from 840 older children themselves by means of a questionnaire which they filled in at school.

The survey was undertaken to assist the Central Advisory Council for Education (England), which, in 1947, was asked by the Ministry of Education to investigate the natural interests and pursuits of children out of school hours, the provision made for them, and the extent to which school work could help to develop these interests.

Thinking chiefly in terms of children's play, one in every two mothers (51 per cent) said that there was not enough for children to do in their districts. 36 per cent of the mothers were quite satisfied with existing facilities and 13 per cent gave qualified answers. Fewer mothers in rural districts (26 per cent) were satisfied than in urban districts (38 per cent).

The main cause of dissatisfaction was that the children had to play in the street; 47 per cent of the mothers said that their children usually played in the street. 46 per cent of the mothers said that there was no park available within easy reach of the children and 52 per cent said that there was no playground. As many as 52 per cent of the children in the sample did not go to any parks and 68 per cent did not go to a playground. Play-centres were almost unknown; only 2 per cent of the younger children (up to the age of ten) and 4 per cent of the older ones ever went to one.

The majority of the children lived within twelve minutes journey from school, so that, allowing for the usual school closing times, children appear to have approximately three to four hours in the evening, as well as the week-end, for their leisure interests.

---

* "Children out of School", by Joy C. Ward. 10s. net.

But children have a good many calls on their leisure-time. Almost all (96 per cent) of the children at grammar schools had homework to do in the evening; 52 per cent of the boys and 39 per cent of the girls did more than one hour per evening. Only one in four of the children at secondary modern and technical schools did any homework, and the majority did less than one hour. Grammar school children—particularly the girls (42 per cent)—had other studies as well, music practice taking up most time.

Apart from homework, both boys and girls had considerable duties at home, the girls more than the boys. Shopping headed the list of duties: 80 per cent of the girls and 68 per cent of the boys did some shopping. Helping at home came next: 78 per cent of the girls and 59 per cent of the boys had some duties at home, which ranged from small tasks like setting meals to being responsible for the family's evening meal. 43 per cent of the girls and 32 per cent of the boys looked after younger children in the family.

Investigating membership of clubs and organizations among the children, Miss Ward reported that children are 'club-minded' by the age of ten, although most youth clubs do not open their doors to children below their 'teens'.

Three-quarters of the children of 11–15 years belonged to one or more club or other organization. Cinema clubs were mentioned more than any other and were most popular at the age of 10–11 years; 22 per cent of the boys and 18 per cent of the girls belonged to them. 13 per cent of the boys were Scouts or Cubs and 16 per cent of the girls were Guides or Brownies. The highest proportion of membership was among the 11–12 year olds.

From the age of thirteen upwards social clubs of various kinds were the most popular clubs and increasingly so with age. Church social clubs began to be important in the 8–10 year age-group (boys 11 per cent, girls 10 per cent). Other social clubs did not show comparable membership until the age of thirteen. Only 1 per cent of children in rural areas belonged to youth clubs compared with 7 per cent in towns.

A small proportion of the 11–15 year old children belonged to clubs which were devoted entirely to sports. More boys (10 per cent) than girls (3 per cent) belonged to these.

Cinema-going was the largest single activity among the children: only one in five did not go at all and those that did not go were mostly the very young ones. Only 6 per cent of the children of eleven and over did not go and less than 1 per cent of the 14-year olds. Most frequent was the weekly visit to the cinema, but 30 per cent of the older boys (11–15 years) and 25 per cent of the older girls went more than once a week. Grammar school children went less than those at secondary modern and technical schools. It seemed that boys and girls went equally as often, though there was evidence to suggest that girls at grammar schools went less than the rest of the children. Boys in the lower economic groups went more frequently than those in the middle and higher groups.

Membership of cinema clubs was found to be strongly associated with frequent visits to the cinema; compared with other children nearly twice as many of the children who belonged to cinema clubs went to the cinema once a week and more than once a week. The films the children (11–15 years) liked best were 'thrillers', murder and mystery films. The girls' second choice was 'musicals', and the boys' second choice was comedies.

Only 6 per cent of the 11–15 year old children said that they did not listen to the radio; one in three listened on the evening prior to the interview with the investigator. Among the younger children 14 per cent of the 5–7 year olds and 8 per cent of the 8–10 year olds did not listen in. Most of the older children (11–15) had hobbies of some sort; only 9 per cent of the boys and 12 per cent of the girls did not mention any.

Reading was more popular with girls than with boys, at all ages. Only 8 per cent of the 11–15 year old children said that they did not read. 28 per cent of the children in the sample belonged to the public libraries.

Football and other games were by far the most popular activities of the boys. 77 per cent mentioned it as one of the four things they liked doing best out of school. Next to this, playing out of doors, walking, and cycling were mentioned by 52 per cent of the boys, and (heading the girls' list) by 59 per cent of the girls. Other interests were considerably less popular with boys, but the girls' interests, lacking a predominating factor such as football, were more evenly divided. Besides playing out of doors, girls liked reading (53 per cent) and indoor activities such as knitting, sewing and playing 'indoors'. The girls' interests were found to lie much more at home than the boys'. Seven out of ten of the boys sought their leisure-time interests away from home compared with about one in three of the girls.

The investigator also made detailed analyses into the interests and activities of children at grammar schools, on one hand, and those at secondary modern and technical schools on the other. Apart from better facilities for play—such as more parks in their own district—the grammar school children's time was more fully occupied. They had, on an average, a slightly longer journey from school, and the majority did more than an hour's homework each night. Many of the girls, in addition, had music practice and other lessons to do. On the other hand, as many grammar school girls helped at home as secondary modern and technical school girls, although more of the latter had to look after younger children in the family. More grammar school girls belonged to the Girl Guide movement, and more played games. Wider interests of grammar school girls were shown also in the fact that membership of such societies as the Young World League and Dr. Barnardo's League was confined almost entirely to them. Membership of hobbies clubs was confined almost entirely to grammar school children; 30 per cent belonged, compared with 12 per cent of the children at secondary modern and technical schools.

Children at secondary modern and technical schools went to the cinema more often than grammar school children, and twice as many of them belonged to cinema clubs. More of the boys and girls at secondary modern and technical schools belonged to no other clubs apart from the cinema clubs.

Some differences were found also in the kind of films and radio programmes which the children liked, though the favourite radio programmes—'Quiz' and 'Variety'—were liked equally by girls and boys at both types of schools.

Since this survey was carried out in the winter months, it is possible, as Miss Ward suggests, that different findings would be made if investigations were continued in a summer period.

Electron Microscopy of Chick Embryo Membrane infected with *PR*-8 Influenza

PREVIOUS studies[1] of tissue sections with the electron microscope have shown masses of particles having the dimensions of the elementary bodies of influenza virus associated with infected cells. These particles have been the expected mixture of spheres and rods with diameters of c. 100 mμ. As seen in the sections, they have seemed to be developing out from, rather than within, cells. This manner of growth and the ease with which it can be observed make influenza-diseased tissues one of the more fruitful objects for the study of how viruses grow.

In the earlier investigation, the virus-like particles were observed both on the chorio-allantoic membrane of chick embryos and in the lungs of mice. They have, however, been found more easily on membranes. A striking feature of infections with freshly isolated strains of virus has been the rapid necrosis that has followed infection, and the difficulty of finding virus particles in the slimy masses of disintegrating tissue that result. For this reason it has seemed worth while, as a next step towards seeing how influenza virus proliferates, to examine the infection of chick embryo membranes using a long-established and well-adapted strain of virus such as *PR*-8.

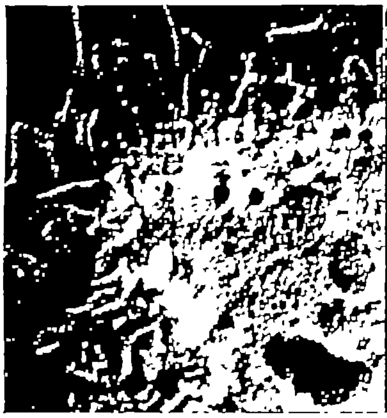
For these experiments the membranes from inoculated embryos were harvested after 48–72 hr. incubation, washed with saline and fixed by immersion for one hour in neutralized 4 per cent formalin–saline. Pieces were dehydrated by passage through pyridine–water mixtures and then embedded in methacrylate[2] polymerized in an oven at 45° C. Sections cut from such blocks were mounted on 'Formvar'-covered grids, the methacrylate was removed with amyl acetate and the resulting preparation lightly shadowed with palladium for examination under an RCA type *EMU* microscope.

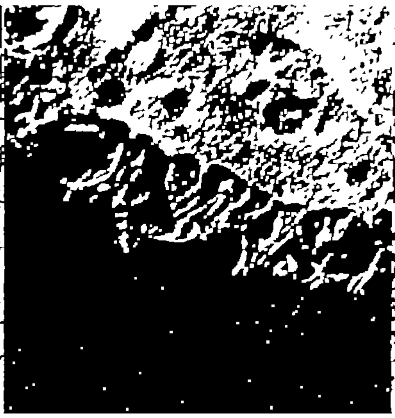
Masses of filaments and spheres having the diameter of virus are to be seen at many points along surfaces of these membranes (Fig. 1). Many of the filaments appear segmented into the spheres. Filaments develop both out from the limiting surface of the membrane (Fig. 2) and between cells. As this latter growth proceeds, it isolates adjacent cells more and more completely from one another; a cell thus desquamated is shown in Fig. 3.

It is obviously of primary importance to try to establish whether the filaments are protoplasmic protrusions from the affected cells or parasitic growths along its borders. It has been difficult to find convincing evidence in the photographs for one or the other of these possibilities; but it is noteworthy that where sectioning has cut through attached filaments, their contents seem continuous with the cellular cytoplasm (Fig. 2). To this degree the filaments and spheres shown in the figures can be thought of as extruded and detached bits of this cytoplasm.

The question naturally arises as to whether these objects actually are the virus particles. After formalin-fixation, they invariably have had the diameters (c. 100 mμ) of the infectious units found in purified suspensions. Large areas of infected tissue were scanned during the present experiments; the particles illustrated could not be found in all membranes, but no other objects the size of virus were anywhere recognized. Healthy membranes have not contained them, but similar particles have been numerous in sections through membranes infected with Newcastle disease virus[3]. In two or three out of several hundred membranes, filaments of the diameter in question have been seen along the borders of membranes that were not diseased with either of these viruses. It is not yet known what were the conditions that produced them.

Using dark-field optical microscopy, Hoyle has seen indications in pieces of excised normal and influenza-diseased chorio-allantoic membrane[4] of what may be the cellular protuberances shown here. It is hard to make too close a comparison between the dark-field observations and the electron micrographs, because particles the size of influenza virus are so small that optical microscopy cannot portray them in their true dimensions even though it may indicate their presence. Nevertheless, the electron microscopic observations thus far made suggest a picture of





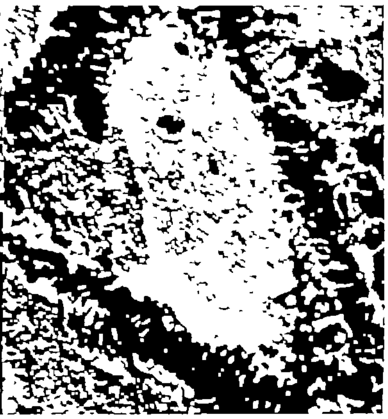


Fig 1. Rods and spheres the diameter of influenza virus along the border of a diseased cell. A few of the rods seem to be segmenting into the spheres. Note the spongy texture of the filaments. × 10,000

Fig 2. Filaments developing out from the periphery of a *PR*-8 diseased cell Where the filaments, too, have been sectioned their contents seem continuous with the cytoplasm of the cell. × 10,000

Fig. 3. Remains of a cell isolated from its neighbours by the filaments that have developed around its borders. × 6,500

developing influenza virus which resembles in many respects that proposed by Hoyle. If the elementary infectious units of influenza actually are cellular fragments, as the electron micrographs indicate they may be, this defines within narrowing limits the views that can be maintained concerning the fundamental nature of influenza virus. The study is being continued.

Action of Living Cells on Cortisone Acetate Crystals

In the course of experiments designed to study the effect of cortisone upon the growth of fibroblasts in hanging-drop tissue culture, it was observed that the cortisone acetate crystals dissolved in the plasma clot.

One drop of fowl plasma and one drop of embryonic extract, both diluted with Gey's saline solution in the proportion of 1 : 2, were mixed with one drop of cortisone acetate (Merck) suspension. This mixture of the three drops was spread out on a cover slip, and a piece of chick embryo tissue 1 mm. in diameter was placed in the centre of it. The cover slip was then affixed to a depression slide, sealed and incubated at 38° C.

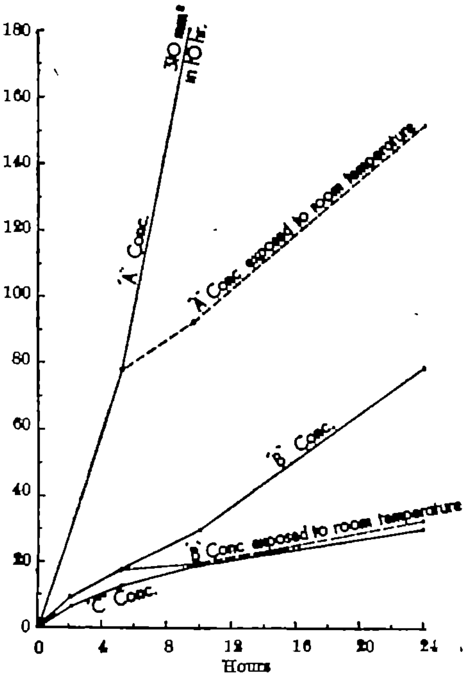

Fig. 1

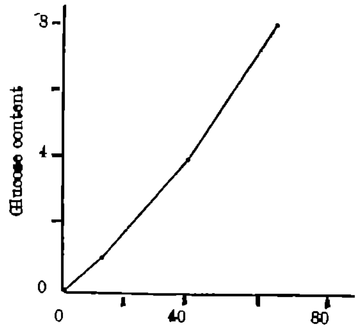

Fig. 2

When a higher concentration of cortisone acetate is used, the plasma clot appears macroscopically turbid, and under the microscope the crystalline form of cortisone acetate may be seen discretely suspended in the otherwise clear plasma clot. With lower concentrations of cortisone it was found that the crystals disappeared after 24 hr. incubation; but in the higher concentrations, only a circular zone around the tissue was cleared of crystals. It was further observed that there was extensive vacuolation of the growing cells which, according to Fisher (1947), may be a sign of depletion of glucose. As a result of this observation, and in view of the fact that a related compound, deoxycorticosterone, is known to be soluble as a glucoside, further series of tissue cultures with increasing amounts of glucose were set up.

The cortisone acetate (Merck) used in these experiments contains 25 mgm./ml. and was diluted with Gey's saline solution containing 0·2 per cent glucose. Cortisone concentrations of 10 per cent (*A*), 20 per cent (*B*) and 40 per cent (*C*) were used. The size of the area cleared of cortisone crystals around the implant up to 24 hr. is recorded in Fig. 1. The series containing 10 per cent cortisone (concentration *A*) cleared rapidly, and after about 12 hr. all the cortisone crystals had dissolved in the plasma clot.

With 20 per cent cortisone (concentration *B*), during the first 24 hr. up to an area approximately 9 mm. in diameter around the implant was cleared and did not change on further incubation. With 40 per cent cortisone (concentration *C*) the area cleared was limited to 5 mm. in diameter.

After 5 hr. incubation, some preparations of each series were taken out of the incubator and further observed at room temperature. As is shown in Fig. 1, the process of clearing was slowed down considerably at the lower temperature. The reason for this may be the slower metabolism of the living tissue at sub-optimal temperature.

In order to observe the effects of increased glucose content, another series of hanging-drop cultures was set up, each containing the 40 per cent cortisone suspension, but the Gey's solution used to dilute the cortisone contained 0·2, 0·8 and 1·6 per cent glucose.

It was found that the higher the glucose content, the greater was the area cleared around the implant. Fig. 2 shows this to be a nearly linear relationship.

When dead tissue instead of living tissue was embedded, the above-described phenomenon did not take place. Cholesterol crystal suspensions used instead of cortisone were not dissolved by the living tissue culture.

These observations indicate that the dissolution of the cortisone acetate crystals is dependent upon chemical changes associated with living tissue, and the fact that glucose is essential to, and promotes, the process suggests that the resultant compound may be cortisone glucoside.

The cortisone used in this experiment was part of a gift kindly made by Merck Co. (Inc.) to the Medical Research Council and the Nuffield Foundation.

Detailed experimental results will be published elsewhere in due course.

The 1·5-A. Reflexion from Proteins and Polypeptides

In a recent issue of *Nature*, Pauling and Corey[1] have raised certain points in connexion with the 1·5-A. reflexion which I reported to be present in proteins of the α-keratin type, in an artificial polypeptide and in hæmoglobin, and to be absent in feather rachis[2]. To their remarks I should like to make the following comments.

Occurrence and significance of the reflexion. In their most interesting and stimulating paper, Pauling, Corey and Branson[3] have given powerful arguments to show that, of all the possible models of polypeptide chain, their newly discovered 3·7- and 5·1-residue helices have the lowest free energy, from which they conclude that these two configurations are the ones most likely to occur in Nature. They have also reported that one of these chains, the 3·7-residue helix, gave favourable agreement with published X-ray data of fibrous proteins and artificial polypeptides of the α-keratin type, and of hæmoglobin. Pauling, Corey and Branson's solution of the stereochemical problem seemed convincing; on the other hand, Bragg, Kendrew and I[4], and others before us, had found that some of the alternative models also fitted X-ray data reasonably well, and it seemed to us that such correlation as Pauling and Corey had obtained with the 3·7-residue helices did not rigorously exclude those other models.

These doubts led me to predict that the 3·7-residue helix, if present in all proteins and polypeptides of the α-keratin type, should give rise to a reflexion at 1·5-A. spacing when the fibre axis is inclined at equal angles to the incident and diffracted rays. None of the models previously proposed would give a reflexion at this spacing. So far my prediction has been borne out by experiment. In addition to the substances for which the reflexion was first reported, Huxley and I have now found it in wool, myosin and actomyosin, Astbury in epidermin[5] and Brown in poly-γ-methyl-L-glutamate[6]. It is interesting that while the exact spacings of all other α-keratin reflexions vary slightly in different substances, this reflexion appears always at the same spacing of 1·50(± 0·01) A. This suggests constancy of the configuration of the main polypeptide chain, no matter what the side-chains are.

MacArthur, in the course of his detailed X-ray studies of fibrous proteins, discovered a reflexion at 1·49 A. in African porcupine quill, but not in Canadian porcupine quill, nor in any other fibre[7]. I did not regard the appearance of this reflexion in African porcupine quill alone as decisive evidence, because this fibre is now known to contain a substantial fraction of a protein of the β-type[8]; to which this reflexion might possibly have been due, and also because MacArthur[7] and Astbury[9] had interpreted the meridional reflexions of porcupine quill in terms of the repeat of different kinds of amino-acids at regular intervals along the chain. I selected polybenzylglutamate as a test case, first because Ambrose and Elliott[10] had shown it to contain predominantly chains of the α-type, secondly because diffraction effects due to the regular repeat of different kinds of amino-acids can be excluded in a simple polymer, and thirdly because the intensity of the reflexion should be high in a substance where all the side-chains are of the same kind. This expectation was confirmed by results.

The points brought out in the communications by Huxley and myself in *Nature*, which I believe to be new and important, are the universal appearance of this high-angle reflexion, in an artificial polypeptide, in such poorly organized fibres as hair and muscle, and in a crystalline protein; its remarkably constant spacing; its disappearance in the β-form; and its decisive character, not in proving the 3·7-residue helix to be correct, but in excluding models which do not have a repeat of 1·5 A. or a multiple of that spacing. I think it is fair to claim that none of these points had been previously realized. Had the existence of this high-angle reflexion in all fibres of the α-keratin type been discovered earlier, there is little doubt that it would have excluded many models of chain which have been put forward and probably led directly to a solution of the type at which Pauling, Corey and Branson arrived largely by stereochemical reasoning.

Reflexions at multiples of 1·5 A. Pauling and Corey[11], and in the statement quoted in their later communication[1], say: "We would expect that side-chains of different kinds on the α helix would repeat at an integral number of residues, corresponding to an integral multiple of residue lengths along the helix axis, about 1·53 A., and that accordingly those orders of basal plane reflexions for which the spacing approximated closely to certain multiples of 1·53 A. would be enhanced in intensity". This would be a quite different feature of the chain from that indicated by the universal and constant 1·50-A. spacing, and one which still appears to require proof. It would require the repeat of the same or similar amino-acid residues at regular intervals, for example, every other or third residue having a large side-chain. The results of partial hydrolysis of proteins, however, do not indicate that such regularities are a feature of protein structure.

Huxley and I have therefore re-investigated the appearance of these reflexions, and our results to date, combined with those of previous investigators, have led us to the following conclusions. (*a*) In polybenzylglutamate and in homogeneous proteins of the α-keratin type, such as myosin and fibrinogen[12], these reflexions are absent. They are also absent in our specimen of porcupine quill, although this does show the 1·5-A. reflexion itself. (*b*) Systems such as hair and porcupine quill which Ambrose and Elliott[8] have recently shown to contain mixtures of α- and β-proteins do show reflexions at spacings which are approximately, but not exactly, small multiples of 1·50 A. Horse hair shows a wide meridional arc at 3·08 A. which is almost certainly due to β-keratin, as its spacing is the same as that of a strong meridional reflexion in feather rachis. The reflexions at 3·08 and 6·19 A. which MacArthur observed in

African porcupine quill both correspond to strong reflexions in feather rachis and may have the same origin. (c) Astbury[13] and MacArthur[7] have shown that reflexions from frog muscle at approximate multiples of 1·50 A. are due in part to collagen and in part to actin. Bear's clam muscle (type II) gives reflexions similar to those of frog muscle which may be accounted for in the same way[14]. In clam muscle (type I) Bear does not list any meridional reflexions below 18·2 A. (apart from the 5·1-A. reflexion)[15]. When such high multiples of 1·50 A. are considered, spacings would have to be known with great accuracy before a correlation could be definitely established.

Feather rachis keratin. I agree with Pauling and Corey that the absence of the 1·5-A. reflexion does not necessarily exclude the presence of 3·7-residue helices. Their remarks have led me to re-examine the X-ray diffraction pattern of feather rachis. Oscillation photographs taken about the normal to the fibre axis indicate that the strong reflexion at 3·07 A. has a structure factor which is about twice as large as that of any other meridional or near-meridional reflexion. The reflexion at 5·53 A., quoted by Pauling and Corey in support of the presence of 3·7-residue helices, is weak and consists of two separate reflexions the normals of which make an angle of about 22° with the meridian. There is no reflexion at 0·75 A., such as would be expected on the basis of the structure proposed by Pauling and Corey[1]. These results suggest that the correct solution may be of the type originally proposed by Astbury and Woods, with chains of the β-type playing a dominant part in the crystalline fraction of the fibre[16].

Action of Terramycin and Chloromycetin on Cholera Vibrio in Mice

Terramycin hydrochloride (Pfizer) was tested in mice inoculated with *Vibrio cholera*. The animals were inoculated intraperitoneally with a suspension of 1 ml. of an 18-hr. old culture; the suspension contained 50 × 10^6 organisms per ml. and 5 per cent mucin (Armour)[1]. These inoculations were fatal in 48 hr. Four strains (Ogawa 41, Inaba 35 and 29, and a Mediterranean Inaba strain) were employed.

In the first series of experiments, in which the antibiotic was administered intraperitoneally in single graduated doses half an hour after the infection, 15 out of 15 animals, infected with the Inaba strains, recovered after treatment with 5–10 mgm./kgm. of terramycin. The strain Ogawa 41 was more resistant and required 15 mgm./kgm. in order to produce a 100 per cent survival.

Larger doses of antibiotic were required to control the infection when administered five hours after inoculation: 15 mgm./kgm. in the case of the Inaba 35 strain, 30 mgm./kgm. for the Inaba 29, the Mediterranean Inaba, and the Ogawa 41 strains. With these quantities, all 15 animals of the series survived.

A period of five hours seems to be the limit of time after infection in which the terramycin is effective. In experiments with the Inaba 35 strain, even 300 mgm./kgm. was ineffective after seven hours from the time of infection.

If administered half an hour after the infection, chloromycetin (Parke, Davis and Co.) was curative in doses of 25 mgm./kgm. in the case of Inaba 35, of 50 mgm./kgm. in the case of the other two Inaba strains, and of 100 mgm./kgm. in Ogawa 41. These results are in agreement with those reported by Gauld *et al.*[2].

Five hours after the infection, 250 mgm./kgm. of chloromycetin was still effective in the case of the Inaba 29 and the Mediterranean Inaba strains (20 mice; 100 per cent survival), but was only partially effective against the Ogawa 41 and Inaba 35 strains (10 mice; 30 per cent survival).

Caulobacter versus *Bacillus* spec. div.

The study of sessile freshwater bacteria induced Henrici and Johnson[1] to draw up a preliminary taxonomic system comprising many sessile species. They brought all these together in one order, Caulobacteriales; *Caulobacter* being the name given to one of the genera. This genus is characterized by the presence of a stalk connecting one end of the elongated bacterial body to a solid substrate and by multiplication by transverse binary fission. The first to describe such a bacterium, without giving it a name, was Jones[2].

Some strains, probably all to be classified as one species of this genus, have been isolated at Delft from tap water. The development of *Caulobacter* can be promoted by adding peptone water to the tap water so as to make a 0·01 per cent solution. The bacterium will then be found at the lower end of its stalk hanging down from the surface of the water. If a thin collodion film, such as is used as a specimen-carrier in the electron microscope, is made to float on the surface, the bacterium attaches itself to the film. To obtain a preparation suitable for the electron-microscope, one merely has to lift the film with a specimen carrier and to rinse it with distilled water[3].

Isolated in pure culture, *Caulobacter* may be cultivated on 1 per cent peptone agar; but single colonies always remain very small. In 1 per cent peptone water the bacteria produce irregular long forms; in 0·1 per cent peptone water more-normal single individuals are obtained. Stalks, however, are very short in a pure culture, and growth is less abundant than might be expected.

Much better growth is obtained if the medium is inoculated simultaneously with some *Bacillus* sp. (for example, *Bac. subtilis* or *Bac. megaterium*). In a combined culture of *Caulobacter* and *Bac. subtilis* strain 'Marburg' in 0·1 per cent peptone water, the latter species is abundant after one day. Gradually, however, *Caulobacter* gains a dominating position. The bacillus serves as a support for *Caulobacter*: one, two, or as many as ten or more may settle on one cell of the bacillus. It is noteworthy that the spores of the bacillus always remain free from *Caulobacter.*

Electron micrographs give a better insight into the relationship of the two species. Occasionally a seemingly healthy bacillus with one *Caulobacter* attached to it is encountered (Fig. 1); most of the bacilli, however, look unhealthy. Finally, little but the cell membrane and the flagella—and in some instances only the flagella—is left (Fig. 2).

The fact that the micrographs give evidence that the stalk is tube-shaped, and apparently contains protoplasm, suggests that it acts as a sucking proboscis, which would imply that *Caulobacter* acts as a parasite to its host bacterium.

Caulobacter, when about to divide, grows a flagellum at its free end. The daughter cell thus is motile and swims rapidly before settling down. After this, a new stalk is formed. Since the flagellum of a sessile specimen, if present at all, is found to be inserted at the terminal end of the stalk, one may assume that a young *Caulobacter* attaches itself with the flagellated pole, and then grows away from the substrate it settled on by narrowing its basal end so as to form a stalk.

The *Caulobacter–Bacillus* relationship is certainly more complicated than can be described in this brief communication.

In more concentrated media, *Bacillus* species can adversely affect the growth of *Caulobacter* up to the point of suppressing it altogether; this is apparently due to chemical alteration of the medium by the metabolism of the bacillus, possibly including liberation of antibiotics.

It is noteworthy that all evidence is in favour of the view that *Caulobacter* is not a cannibalistic bacterium.

A further account of these observations will be published elsewhere. This work is being supported by a grant from the Netherlands Organization for Pure Research (Z.W.O.) to the Technical Physics Department T.N.O. and T.H., Delft.

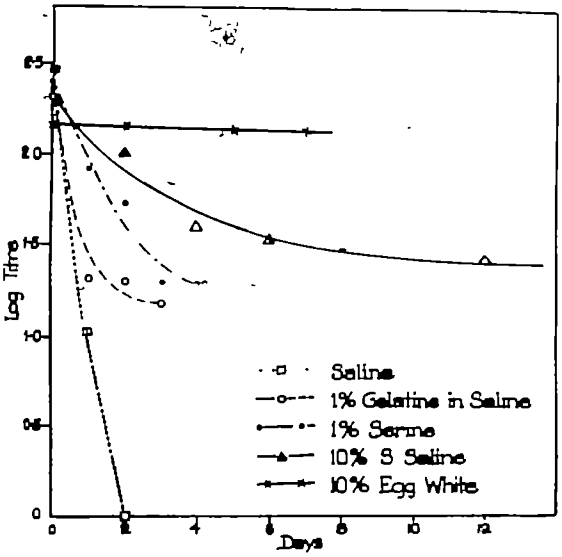
An Improved Diluent for the Production of African Horse-sickness Virus Vaccine

It is the general practice among virologists to use 10 per cent normal serum saline as the diluent of choice for the preparation of virus emulsions. In keeping with this practice, horse-sickness vaccine consists essentially of suitably prepared emulsions of selected virus strains in 10 per cent normal horse serum diluted in the same fluid to contain per dose an adequate number of infecting doses of these strains. Since the efficacy of the vaccine is dependent entirely upon the injection of living virus, it is essential that the diluting fluid should be one which favours longevity of the virus. Of a number of media tried, the 10 per cent horse serum saline was found to be the most desirable (Alexander, personal communication).

For various reasons, which will be discussed in a subsequent publication, it was decided to reinvestigate the problem. Tests were carried out using different concentrations of salts, salt mixtures, sugars, gelatine, amino-acids and egg-white. Viability of the virus on storage at 35° C. for periods of seven to twelve days as determined by *in vivo* virus titrations was used as the criterion of suitability of the various diluents.

It was found that solutions of inorganic salts and sugars have a pronounced lethal effect upon the virus. Gelatine and a number of amino-acids in a concentration of 0·1 per cent did not inactivate the virus; but none favoured viability to the same extent as 10 per cent serum saline. Ultimately, it was found that 10 per cent egg-white in $M/50$ phosphate buffer pH 7·5 was the diluent of choice.

In the accompanying graph are given the viability curves in different media of one strain of horse-sickness virus (strain 1,180), one of the least stable of the strains investigated. In the curves, the logarithm of the virus titre is plotted against the time in days of storage at 35° C. It will be seen that over a period of seven days the virus titre in 10 per cent egg-white phosphate buffer remained practically constant, whereas a variable reduction in titre down



to complete inactivation occurred with the other media tested. These results have been confirmed in other experiments.

This preliminary report is submitted in the hope that use of this medium may be of value to other workers in the field of viruses, particularly those handling the more fragile viruses such as influenza and rinderpest, or those engaged upon the preservation of virus emulsions by freeze-drying or other means.

Erythrocyte Antibodies as a Cause of Abortion in Cattle

It is well established that bacterial antibody does not cross the bovine placenta, and that although bacterial antigens can leave the non-pregnant uterus and enter the blood stream[1], it is unlikely that they would normally leave the pregnant uterus. The barrier to antibody and antigen transfer is generally ascribed to the effect of the multi-layered epitheliochorial placenta of the bovine and the large size of the molecules concerned. Because of this it has been generally thought that hæmolytic disease of the fœtus was unlikely to occur in cattle; but hæmolytic disease of the new-born might follow sensitization of red blood corpuscles by colostral antibody as it does in the mare[2,3]. Although in cattle hæmolytic disease has not been recognized, there are a number of conditions of the fœtus such as some forms of early abortion, macerated fœtus, hydrops fœtalis, and premature still-birth, which have not been explained on other pathological grounds and which show certain features not altogether dissimilar to human hæmolytic disease. Normal agglutinogens comparable to the *ABO* groups of humans are believed to occur only rarely in cattle[4]; but a very large number of erythrocyte antigens have been defined by the production of immune sera in cattle and rabbits[5].

In view of these latter facts, and because it seems that another entrance of antibody to the fœtus than that via the vessels of the fœtal placenta may not be impossible[6], an investigation of the possible occurrence of hæmolytic disease in cattle was commenced. Sera from cows in several herds were tested by means of the ordinary *Rh* saline agglutination technique[7] against the red blood corpuscles of bulls to which they were or had been in calf. In the first herd (*A*), where a large number of abortions had occurred which had not been explained after thorough investigation, six positive sera out of forty-four were found. Four positive sera were found in a second herd (*B*) of ten animals where there had been long irregular œstrous cycles but no recognized abortions. A third group (*C*) of nine cows which were infertile, but the œstrous cycles of which had been regular, showed only one positive serum, and ten cows (*D*) which had all become pregnant at the first insemination from the same bulls as were used in herds *B* and *C* showed only one positive serum.

An immune serum was then made to the red blood corpuscles of a bull (*R*) which was of low fertility but which was producing apparently normal semen, and in which no infectious disease could be detected. This serum was produced in a heifer following successive intravenous injections of whole citrated blood. The maximum titre obtained was 1/160 in saline, and 1/640 in albumen[7]. The antibody-level fell rapidly, but could be raised by further injections, although not to the original high level. Tests with this serum indicated that the red blood corpuscles of the bulls *P* and *G* of herd *A* were probably antigenically similar to those of bull *R*. Two females, the red blood corpuscles of which were not agglutinated by the artificial immune serum, were mated to bulls *P* and *G* and became pregnant. Two others whose red blood corpuscles reacted similarly were mated and became pregnant to bull *R*. Sera from these animals were tested weekly as before against the erythrocytes of bull *R*. Three of them agglutinated the red blood corpuscles of bull *R* at some tests; but the reaction took place only in undiluted serum, except on one occasion in one animal when the titre rose to 1/2, and on another in another animal when it rose to 1/4. The remaining animal which was pregnant to bull *P* was transfused on the 100th and 115th days of pregnancy with 500 c.c. and 250 c.c. of citrated whole blood from bull *R* with no effect except a rise in the serum agglutinin titre to 1/16 after two weeks. The titre fell to 1/4 after a further week. This animal, and that pregnant to bull *G*, were each transfused on the 185th and 191st days of pregnancy respectively with 250 c.c. of citrated whole blood from bull *P*. Signs of commencing milk secretion were observed six days later in the former animal. The transfusions were repeated nine days later using 25 c.c. of blood for the animal pregnant to bull *P* and 225 c.c. for that pregnant to bull *G*. Two days later both animals aborted. No unlysed red blood corpuscles could be found in one fœtus. In the heart blood of the other there was an abnormally large number of erythroblasts. The serum agglutinin titre in both cases was 1/4 at abortion and rose after two weeks to higher than 1/32 (beyond which it was not titrated). The two animals which were pregnant to bull *R* were each transfused with 250 c.c. of his citrated whole blood on the 125th, 131st, 145th and the 103rd, 109th and 123rd days of pregnancy respectively. The serum titre of the former rose to 1/8 and she aborted eight days after the third transfusion. That of the latter rose to 1/128 after the third transfusion and she aborted three days later. In each case the heart blood of the fœtus contained large numbers of erythroblasts.

Examination of the colostrum from these animals showed that the antibodies were concentrated by the udder. Typical examples are those where the serum titre was 1/4 and the colostral titre 1/20, and where the serum titre was 1/128 and the colostral 1/640. The colostral antibody was transferred to a calf's blood by feeding colostrum during the first two days of life.

Titration of the sera in saline against bull *R*'s erythrocytes with rabbit complement added gave hæmolysin titres similar to those of the agglutinins.

Throughout these experiments steps were taken to exclude infection and other factors as causes of abortion. The physical reaction to transfusion was in no case very great, being limited to a slight and transient dyspnœa and pyrexia, and it does not seem likely that abortion was due to transfusion *per se*.

From the evidence obtained it would appear that maternal circulating erythrocyte antibodies can cause abortion. The mechanism by which this is brought about may either be a reaction at the cotyledons or the result of an actual transference of antibody to the fœtal circulation. The antibody evidently becomes concentrated in the colostrum and is capable of being absorbed by the new-born calf. The interpretation of the full significance of these observations in relation to disease of the fœtus and young calf must depend on further investigation.

Transfer of Bacterial Antibodies from the Hen to the Chick

During an investigation on the transfer of antibodies against *Salmonella pullorum* from the hen to egg yolk, non-agglutinating antibodies as well as agglutinins were found in the hen's serum and in the yolk. The non-agglutinating antibodies were detected in serum by the method of Morgan and Schutze[1]. The serum was diluted serially, and an equal volume of antigen added to each dilution; after 18 hr. at 53° C. any agglutination was noted, and the antigen in those tubes in which there was no agglutination was washed; to each of those tubes was added anti-avian-globulin serum. If the antigen had been sensitized by the unknown serum, it was agglutinated in the presence of the anti-avian-globulin serum. Antibodies of this type are referred to as non-agglutinating antibodies.

Egg yolk was tested for the presence of this type of antibody by first preparing an extract of the yolk: After exposing the antigen to serial dilutions of this extract, it was mixed with the serum of a rabbit which had been inoculated with yolk livetin. Samples of both serum and egg yolk from a small flock of hens that had been inoculated intravenously with killed *Salm. pullorum* were tested for antibodies. The titres of non-agglutinating antibodies in both sera and yolks were 7 to 34 times greater than the corresponding agglutinating titres.

A similar experiment has been carried out in which serum and yolk samples from three groups, each of four hens, inoculated either intravenously, subcutaneously or intramuscularly, were examined for agglutinating and non-agglutinating antibodies. In hens inoculated intravenously, the titres of non-agglutinating antibodies in serum and in yolk were approximately equal, but the agglutinin titre of yolk was much lower than that of serum. The sera of the hens inoculated by the subcutaneous and by the intramuscular route contained agglutinating and non-agglutinating antibodies to about the same titre as in those inoculated intravenously; but there was practically no antibody of either kind demonstrable in yolk. The difference in the titres of the yolks of eggs from the hens inoculated by the subcutaneous or intramuscular route as compared with the intravenous route was consistent and very marked. During an experimental period of sixty days the yolks of seventy-six eggs from intravenously inoculated hens all had non-agglutinating titres varying from 80 to 2,560. During the same period more than ninety eggs from hens inoculated intramuscularly and subcutaneously were similarly examined; the yolks of the majority of these eggs had titres of less than 10 and the remainder had titres of only 10 or 20.

Preliminary observations on a limited number of embryos and newly hatched chicks have indicated that antibody passed from the egg to the chick is largely of the non-agglutinating type.

The method by which protein accumulates in the rapidly developing hen's ovule is not clearly understood[2]; but there is evidence to suggest that the protein molecule is hydrolysed by proteolytic enzymes as it passes through the follicular epithelium into the ovule[3]. Similarly, the transfer of protein from the yolk to the developing embryo is associated with proteolytic enzymes in the yolk, particularly cathepsin, which reaches maximum activity at about the fifteenth day of incubation. Rosenheim[4] has shown that under suitable conditions trypsin, pepsin and papain destroy *Salm. typhosum* 'O' agglutinins in horse serum.

With these considerations in mind, experiments have been carried out on the action of trypsin on both

EFFECT OF TRYPSIN ON AGGLUTINATING AND NON-AGGLUTINATING ANTIBODIES IN HEN SERA

A = titre of agglutinating antibody; *NA* = titre of non-agglutinating antibody.

agglutinating and non-agglutinating antibodies to *Salm. pullorum* in hen's serum. The results of some of these experiments are shown in the accompanying table. By mixing a suitable concentration of trypsin with serum and incubating at 37° C. for one hour at a *p*H of 8·5, it was possible to reduce and even destroy all demonstrable agglutinins without affecting the titres of non-agglutinating antibodies.

Details of experiments on the transfer of antibodies from the hen to the chick via the egg and the relationship between agglutinating and non-agglutinating antibodies will be published elsewhere.

I am much indebted to the Scientific Director of the Animal Health Trust and to the Director of the Trust's Poultry Research Station for their kindness in releasing me from my routine duties to undertake this work in Cambridge.

Glucose and Lysogenesis in *Bacillus megatherium*

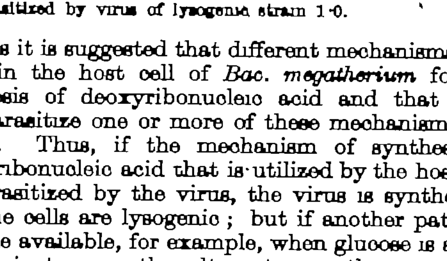
Cells of *Bacillus megatherium* strain 1·0 can carry on metabolic activity, including multiplication, simultaneously with virus formation, for an infinite time; this balance between the cells and their virus is called lysogenesis. Evidence that lysogenic *Bac. megatherium* strain 1·0 can return to the normal uninfected state on a glucose nutrient medium was presented by Ehrlich and Watson[1]. Further study of this phenomenon showed that other sources of carbon, such as fructose, maltose, sucrose, glycerol, pyruvate and succinate in the basal medium all cause recovery from the lysogenic state. In postulating an explanation for this behaviour, it was thought that the virus and the source of carbon might compete for organic phosphate and that the virus was the weaker competitor. The work of Kozloff and Putnam suggested such a hypothesis[2]. However, initial studies showed that this hypothesis could not explain the effect of glucose on lysogenic *Bac. megatherium* strain 1·0.

Glucose in alkaline nutrient agar at *p*H 8·0 was found to inhibit the growth of the lysogenic strain, whereas the uninfected parent strain was not inhibited. Of other sources of carbon that were added to the alkaline medium, only glucose-6-phosphate had an inhibitory effect on growth of the lysogenic strain. Fructose, fructose-6-phosphate, hexose diphosphate, α-glycerophosphate and glycerol did not inhibit growth. Evidence that at least some of these intermediates of glycolysis can be utilized rests in part on the fact that resting-cell suspensions oxidized hexose diphosphate, glucose-6-phosphate, fructose-6-phosphate and phosphoglycerate. Also, 0·01 *M* sodium fluoride prevented the formation of lactic acid from glucose by resting-cell suspensions of uninfected *Bac. megatherium*.

These results suggest the following explanation for the effect of glucose. When glucose is present in a medium that contains a full complement of organic nitrogen compounds, as in nutrient agar, deoxyribonucleic acid might be synthesized via a degradation of glucose-6-phosphate to gluconate-6-phosphate, arabinose-5-phosphate, deoxyribose-5-phosphate, and deoxyribose-1,5-diphosphate, thence to nucleotides and nucleic acid. Such a degradative pathway has been suggested, at least in part, by Dickens[3]. If glucose is present in a synthetic medium, or if the cells are grown on nutrient agar without glucose, the deoxyribose in the deoxyribonucleic acid is probably synthesized by a condensation pathway involving two and three carbon compounds. In fact, Racker[4], and Marmur and Schlenk[5] have shown that certain bacteria can form pentose by a condensation of two and three carbon compounds. Thus, if the virus in lysogenic strain 1·0 of *Bac. megatherium* parasitizes the condensation pathway to deoxyribose and not the degradation pathway, lysogenicity will be lost when glucose is added to nutrient agar at *p*H 7·0, and the degradation pathway is opened. If the glucose nutrient agar is at *p*H 8·0, the virus with the help of the high *p*H can prevent the host cell from utilizing either the degradation or condensation pathway, and growth is prevented. As expected, this inhibition occurs with glucose-6-phosphate but not with other intermediates of glycolysis.

Theoretically, it should be possible to isolate a strain of *Bac. megatherium* which will remain lysogenic in the presence of glucose in nutrient agar. Indeed, eight such strains have been isolated from nutrient agar containing 0·01 *M* glucose. These strains yield virus after repeated transfers on glucose nutrient agar and are resistant to infection with stock virus. However, these strains remain lysogenic on nutrient agar without glucose.

Proposed Pathways for the Synthesis of Deoxyribonucleic Acid by the Host Cells of *Bacillus megatherium*



* Parasitized by virus of strains that remain lysogenic on glucose agar but not of strain 1·0.

† Parasitized by virus of lysogenic strain 1·0.

Thus it is suggested that different mechanisms may exist in the host cell of *Bac. megatherium* for the synthesis of deoxyribonucleic acid and that virus can parasitize one or more of these mechanisms (see chart). Thus, if the mechanism of synthesis of deoxyribonucleic acid that is utilized by the host can be parasitized by the virus, the virus is synthesized and the cells are lysogenic; but if another pathway is made available, for example, when glucose is added to nutrient agar, the alternative pathway will be used and lysogenesis will be lost.

Occurrence of Antifungal Substances in *Brassica rapa*, *Brassica oleracea* and *Beta vulgaris*

SINCE roots and tubers contain different substances which are easily assimilable by many micro-organisms, the question arises whether the mechanical protection by the few outer cell layers of the cortex is sufficient to prevent infections from the surrounding soil, or whether the plant produces antibacterial and antifungal substances to increase its resistance against microbial invasion.

Antifungal substances have been isolated from the tubers of *Brassica rapa rapifera*, *Brassica oleracea gongylodes* and the fleshy roots of *Beta vulgaris*. In the first two cases, the presence of the active substances was strictly limited to the superficial cell-layers, whereas the interior parts were practically free from it; this seems to point to the hypothesis of antimicrobial protection referred to earlier.

In the case of *Brassica rapa* the substance, which we have called 'rapine', could be isolated by disintegrating the peelings in a blendor and subjecting the mass to steam distillation. From the distillate a yellow oily substance could be extracted with ether; the yield amounted to 4 mgm. per 100 gm. of fresh peelings. The substance had the characteristic penetrating smell of turnips. The solubility in water was low and, mixed with malt agar, a concentration of 1 : 10^5 was sufficient to prevent the growth of different fungi and yeasts. At this concentration, rapine did not possess any antibacterial activity against *Escherichia coli*, *Micrococcus aureus* and *Bacillus subtilis*. This specific antifungal activity of rapine was used to check so-called pure cultures of phytopathological fungi for the presence of bacteria, which otherwise is sometimes rather difficult.

As *Trichophyton rosaceum*, a typical parasite of man and various animals, is readily inhibited by rapine, the pharmacological activity of this substance will be a matter of further examination. The following fungi were tested: *Aspergillus niger*, *Aspergillus oryzea*, *Botrytis* sp., *Ceratostomella pilifera*, *Fusarium oxysporum*, *Fusarium solani*, *Penicillium notatum*, *Rhizopus nigricans*, *Trichophyton rosaceum* (growing on Sabouraud agar), *Verticillium cinnabarinum*. Of these, *Fusarium oxysporum* proved to be the most susceptible. The yeasts tested were: *Saccharomyces cerevisiae*, *Saccharomyces lactis* Dombrowski, *Schizosaccharomyces* Pombe, *Cryptococcus lattila* and *Cryptococcus utilis*, all of which were readily inhibited by a concentration of 1 : 10^5 of rapine.

The active principle from *Brassica oleracea gongylodes* was prepared in the same way as rapine. It proved to be a yellowish, solid substance, also slightly soluble in water and with an intense smell of Swedish turnips. It inhibited the growth of the same micro-organisms as did rapine; its activity, however, seemed to be somewhat less pronounced, as in the cases of *Penicillium notatum* and of *Fusarium oxysporum* the critical concentration was [illegible] : 10^4.

From *Beta vulgaris* a crude preparation was made which was especially inhibitive against *Fusarium* sp. This substance was not volatile with steam, was not deteriorated by boiling, was soluble in water and insoluble in ether. It could be extracted from the cortex as well as from the inner part of the root.

Further studies in this field are in progress.

Thanks are due to the Central Bureau voor Schimmelcultures, Baarn, for supplying us with pure cultures of a number of the above-mentioned fungi.

'Lactobacillin', an Antibiotic from Lactobacilli

A SURVEY of streptococci has already shown that the lactic group are the most powerful antibiotic producers[1]. It was of interest to see whether antibiotics are also produced by lactobacilli, especially since Grossowicz, Kaplan and Schneerson[2] have already reported the existence of such substances. Young Gruyère cheese samples from different areas of France were used as one of the sources of these lactobacilli. 40 antibiotic-producing strains, about 3 per cent of the total number of strains tested, have been isolated in pure culture. These gave zones of inhibition 20–30 mm. in diameter when assayed by the cylinder plate method with *Staph. aureus* as the test organism.

One of these organisms, which is homofermentative and resembles *L. helveticus*, is being investigated in further detail. In peptone–glucose broth, containing 0·01 per cent Tween 80, which appears to be essential, supplemented with tomato juice, whey or malt extract, it grows well at 30° C., 37° C. and 43° C., the lower temperatures are, however, more conducive to good yields of antibiotic. Yeast–glucose broth supports good growth at 43° C., but the yeast extract is inhibitory to growth at lower temperatures, and inhibits production of antibiotic at all temperatures of incubation.

With dilution assays in plain nutrient broth, in which the test organism grows well but the lactobacillus does not grow, titres of 1/1,280 were frequently obtained. Against *Staph. aureus* this culture-fluid appears to be about twenty times more powerful than nisin[3]; it is, however, very heat-labile.

We are greatly indebted to G. Mocquot, of the Station Centrale de Technologie Agricole, Paris, for supplying the samples of Gruyère cheese.

Urease Metabolism in *Citrullus*

SINCE the speculations by one of us[1] as to the function of urease in *Citrullus* seeds appear to have aroused interest, we feel we ought to report that further work has shown the original hypothesis (that urease is a reserve protein) to be untenable. We remain unconvinced that the metabolism of urease in *Citrullus* is connected with the metabolism of urea or its derivatives; but it does not appear to be a normal seed-reserve. First, we find that the protein content of the cotyledons of seedlings grown in a nitrogen-free culture medium may fall in eight days to about half its initial value; but the urease content may remain unchanged. Secondly, if seedlings are grown under optimal conditions in soil, we find in the cotyledons no appreciable change in major nitrogen fractions over ten days; but a reduction in urease begins to be apparent at about the fourth–sixth day, followed by a rapid fall almost to zero at about the eighth day. The rapid rise in water-content from about the fourth day shows that this is the time when cell-extension and vacuolation begin; and since Brown and Broadbent[2] have shown that this is a time of considerable metabolic activity, it seems likely that disappearance of urease is connected with its onset.

Moreover, examination by Granick's[3] histochemical method shows that the urease is retained in the bundle-sheaths (the cells of which enlarge relatively little) long after it has disappeared from the mesophyll; detached cotyledons, which expand more slowly than do cotyledons attached to the seedling, also lose their urease more slowly; and etiolated seedlings, the cotyledons of which do not expand, retain their urease for at least thirteen days. In general, the urease metabolism appears to be bound up with the development of the cotyledons rather than with that of the seedling as a whole; and we are attempting to identify more closely the particular process with which it is associated.

We should like to express our gratitude to the Ferry-Morse Seed Co. of California for their generous gift of the seeds used in this investigation.

Extraction of Chloride from Mammalian Skin

In the course of an investigation into the distribution of chloride between blood plasma and skin in the cat, difficulty was encountered in determining the chloride content of the skin. Digestion of the tissue in concentrated nitric acid is impracticable owing to loss of chloride; the tissue proved to be too tough to be ground in trichloracetic acid, which is the standard procedure with other tissues. Freezing before grinding had no helpful effect and cutting the tissue into very small fragments before grinding was, though successful, both laborious and time-consuming; mincing was impracticable owing to the relatively small samples which could be used.

By chance, it was found that a sample of skin which had been dried for 18–24 hr. at 105–110° C. for determination of its water content was quite readily macerated if left in 10 per cent trichloracetic acid a few minutes before being ground. The same effect was produced by drying cat's skeletal muscle, which in the fresh state is much more resistant to maceration than is frog's muscle. On the other hand, liver and kidney, which can be readily macerated in the fresh state, were considerably toughened by the drying process. Thiocyanate was also stable in skin during the drying process and could be determined in the trichloracetic acid filtrate. Since the ease with which a tissue can be handled undoubtedly affects to some extent the amount of attention which is bestowed upon it, the observation now made may be of use to others.

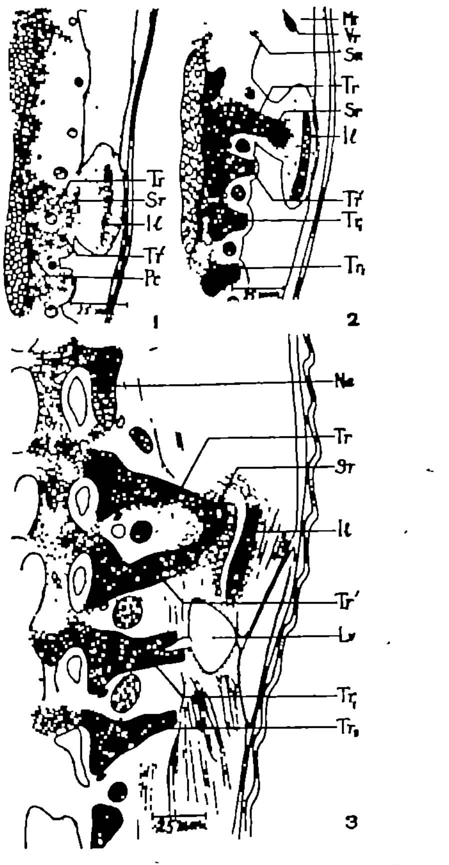
Sacral Ribs of Lacertilia

The sacral ribs of Lacertilia have been for many years the subject of discussion by zoologists. Some consider that the transverse processes of the sacrum are homologous with the ribs of the presacral region[1,2]. Siebenrock[3] made a thorough study of this subject and came to the conclusion that the first sacral vertebra of Lacertilia possesses ribs instead of transverse processes. Moodie[4], however, states quite clearly that there are no sacral ribs in modern lizards. According to him lizards "occupy an isolated place among all other known reptiles in not having any sacral ribs whatever". He considered the processes carried by the sacral vertebræ as transverse processes and not ribs. A similar conclusion was arrived at by Huene[5]. Later, Moodie[6] referred to this view again,



Il, Ilium; *Lv*, large vesicle opposite the transverse process of the first tail vertebra; *Mt*, Myotome; *Ne*, neural arch; *Pc*, primary centrum; *Sn*, spinal nerve; *Sr*, sacral rib; *Tr*, *Tr'*, *Tr₁*, *Tr₂*, transverse process of the sacral, secondary sacral, first caudal and second caudal; *Vr*, ventral rib and suggested that a study of the stages of chondrification might show evidence of the presence of sacral ribs in lizards. In spite of this suggestion by Moodie, most workers in this field have accepted Moodie's earlier conclusion as definite and maintained that there are no sacral ribs in Lacertilia. El-Toubi[7], however, has reported evidence of sacral ribs.

In view of this controversy, the study of the ribs of the sacral region of *Chalcides ocellatus* was suggested by the late Prof. Naef. Different embryos of *C. ocellatus* varying in length from 14 to 45 mm. have been studied in transverse as well as in horizontal sections. I find that the sacral ribs are quite distinct and separate from the transverse processes (Fig. 1). Each rib is a compound one formed from a dorsal rib rudiment and a ventral rib rudiment which fuse early in the connective tissue stage, forming the sacral rib, which extends downwards and backwards. Thus, the sacral rib chondrifies and becomes united with the transverse process of the sacral vertebra (Fig. 2).

At the same time the transverse process of the secondary sacral vertebra extends anteriorly and downwards and thus becomes connected with the sacral rib. Thus the two transverse processes of the sacral and the secondary sacral become united by the sacral rib, which articulates with the ilium (Fig. 3). A detailed account of this work will be published elsewhere.

Structure of $Cu_{32}Al_{19}$

POWDER photographs show that the deformed gamma structure $Cu_{32}Al_{19}$ has 51 atoms in each of the pseudo-cubic unit cells; it is closely related to the cubic structure of Cu_9Al_4 with 52 atoms per unit cell[1]. Whereas the latter is found with 21/13 or 22/13 electrons per atom, the deformed structure takes up to 89 electrons to 51 atoms. The complex quantities may be approximately simplified to the ratios 5/3 and 7/4 respectively; these improper fractions correspond to the monotonic sequence[3] $(2n - 1)/n$. (Cu is monovalent, Al trivalent.)

The loss of atoms follows the simple rule that each additional electron per unit cell replaces one atom[4]. It is achieved by the substitution of one atom of aluminium for two atoms of copper. Thus we have the following sequence:

Formula	Symmetry	Atoms	Electrons
$Cu_{34}Al_{18}$	cubic	52	88
$Cu_{33}Al_{18\frac{1}{2}}$	monoclinic	$51\frac{1}{2}$	$88\frac{1}{2}$
$Cu_{32}Al_{19}$	monoclinic	51	89
$Cu_{31}Al_{19\frac{1}{2}}$	rhombohedral (?)	$50\frac{1}{2}$	$89\frac{1}{2}$
$Cu_{30}Al_{20}$	rhombohedral (?)	50	90

The total number of atoms and electrons remains constant at exactly 140. The numbers of atoms in the monoclinic phase falls from $51\frac{1}{2}$ to 51, while the rhombohedral phase contains $50\frac{1}{2}$ or 50 atoms per unit cell. The Brillouin zone is the same as for Cu_9Al_4, the number of electrons per unit cell rising to a maximum of 90, which agrees exactly with the number of states required to fill the first zone.

All the copper and aluminium atoms in $Cu_{32}Al_{19}$ have definite locations, and it is this fact which leads to the abnormally low symmetry. The extremely peculiar mode of atomic distribution cannot possibly be explained by the size factor, as copper and aluminium atoms are too nearly equal for it to have any effect. The real explanation is to be sought in the electronic factor, each individual free valence electron occupying a definite lattice site[2]. Thus for a complete elucidation of the structure, it is necessary to locate 32 copper atoms, 19 aluminium atoms and 89 electrons.

So far as can be ascertained at present, it appears that the free valence electrons are grouped around the aluminium rather than the copper ions, so that on the whole each aluminium ion retains three negative charges while each copper ion retains one negative charge, but they are usually shared by neighbouring atoms. Thus the structure remains electrically neutral at every point.

The space-group is in all probability *Cm*, and this means that the crystal unit must be doubled, a second set of 51 atoms being required in order to complete the full symmetry with a translation (000, $\frac{1}{2}\frac{1}{2}0$). The true monoclinic cell of $Cu_{32}Al_{19}$ therefore contains 102 atoms, of which eleven groups of four atoms and ten groups of two atoms are copper and seven groups of four atoms and five groups of two atoms are aluminium. (These groupings are subject to confirmation by a complete structure analysis.)

The symmetry degradation is most easily considered as occurring in stages, thus:

$$P\,\bar{4}3\,m \to P\,\bar{4}2\,m \to C\,\bar{4}\,m\,2 \to C\,mm \to C\,m.$$

The pseudo-tetragonal indices of the cubic line 72 (660, 822) on the cobalt powder photograph are readily ascertained. There are three successive reflexions comprising 660 α_1, (660 α_2 + 606 α_1) and 606 α_2. 822 is too weak to be observed. For tetragonal symmetry ($P\,\bar{4}2\,m$) line 48 (444) would not be resolved, but in the orthorhombic unit cell ($C\,mm$) this becomes 804 and 084 and the reflexions are blurred. A detailed examination is required using vanadium radiation, in order to obtain the exact dimensions of the unit cell, and the monoclinic angle (β).

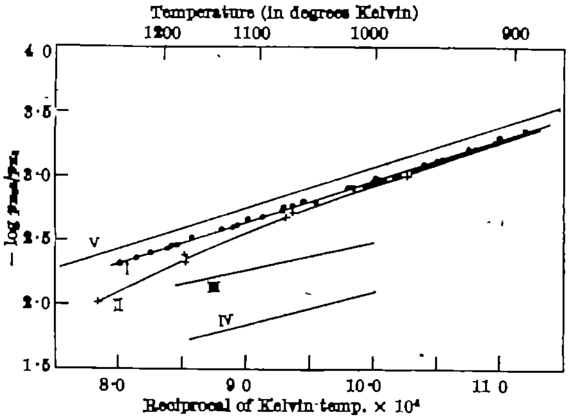
Thermodynamics of Ferrous Sulphide

THE free energy of formation of β-ferrous sulphide has recently been investigated by us as part of a wider study of the thermodynamics of metal sulphides and sulphide mixtures. In view of the metallurgical importance of ferrous sulphide, the results so far obtained are reported here, although it is intended to publish the results of the whole investigation when completed.

The procedure adopted was to measure the composition of gas mixtures of hydrogen and hydrogen sulphide in equilibrium with powdered iron and ferrous sulphide heated to temperatures ranging from 720° to 1,258° K. The gases were circulated over the solids in a closed system, at such a rate that the steady concentration of hydrogen sulphide produced was unaffected by a twofold change in the flow rate, in either direction. Errors due to thermal segregation were therefore avoided.

Radiosulphur was used so that the gases could be analysed continuously by gas counting. It was thus easy to follow the attainment of equilibrium, and the effect of rate of flow on the segregation of the gases in traversing the thermal gradient from the even zone of the furnace to the counter, which was at room temperature. It was found that, even at the lowest temperature used, equilibrium between the gas and solid phases was rapidly attained.



I, Present work; II, Cox, Bachelder, Nachtrieb and Skapski; III, Jellinek and Zakowski; IV, Britzke and Kapustinski; V, Kelley

The results above 890° K. are shown in the accompanying graph, together with those of other workers who have used this equilibrium[1-3]. The values of p_{H_2S}/p_{H_2} are considered accurate to ± 3 per cent, the errors in the counting, analysis and temperature measurement all being included. When combined with data for the free energy of formation of hydrogen sulphide[4], our results yield the following equation for the free energy of formation of two moles of β-ferrous sulphide from iron and diatomic sulphur gas,

$$\Delta G^{\circ}_{720-1,261^{\circ}\text{K.}} = -71,820 + 25\cdot12\,T \text{ cal.}$$

It will be seen that the results of Cox, Bachelder, Nachtrieb and Skapski[1] agree closely with ours, except at the higher temperatures. We consider that this difference is mainly due to thermal segregation at their rate of flow[5], the error attributable to this being 25 per cent in the H_2S/H_2 ratio at 1,200° K. Under static conditions, the error due to segregation would be about 100 per cent at 1,200° K., and this would be sufficient to account for the results of Jellinek and Zakowski[2] at 1,183° K. We cannot account for their results at 1,003° K., or the results of Britzke and Kapustinski[3], on the basis of thermal segregation errors alone.

Kelley[4] has developed an equation for the free energy of formation of ferrous sulphide on the basis of the heat of formation and heat capacity data available in 1936. Curve V in the figure shows that the results derived from this are in fair agreement with our own.

The work reported here was done when we were on the staff of the British Iron and Steel Researcl Association, and we are indebted to its Director fo permission to publish these results.

Rotatory Dispersion Measurements with a Unicam Spectrophotometer

Photo-electric polarimeters are not yet availabl commercially, although several types have bee described in recent years[1]. Between about 4500 an 6500 A. there is no particular advantage in usin such instruments, since in this region visual spectropolarimeters are very accurate and convenient; bu for longer and shorter wave-lengths, photo-electri methods are less tedious than the older photographi ones. We are interested in the red and near infra-re for the extension of studies on the Cotton effect fo blue nitroso compounds[2], and we set out to adapt Unicam spectrophotometer for measuring rotator dispersion by adding two Glazebrook prisms and graduated circle. The arrangement has proved t be so satisfactory for our work that we feel justifie in making this preliminary communication.

In the Unicam instrument there is a passag (between the monochromator and the cell compartment) into which the polarizing prism can be fitted but the cell compartment is not long enough t house the other prism as well as the observation cell Accommodation for the analyser is therefore provided in a separate unit which is constructed so a to make the apparatus completely light-tight. Th prism is mounted in a rotatable tube between th central aperture of the graduated circle and a simila hole cut in a rectangular plate held to the circle b three pillars. Rotation of the prism is controlle by an arm which carries a vernier reading to 0·02 When the analyser unit is inserted in the instrument the rectangular plate forms a new back for the ce compartment, and the graduated circle is fixed i front of the photocell box.

The polarizer and analyser are adjusted visuall so that when they are crossed the scale reads approximately 0°. The actual zero is found by the 'metho of symmetrical angles'[3] in the following way (1) place cell containing solvent in light beam (2) turn transmission scale to 100 per cent; (3) se wave-length scale to desired value; (4) set analyse to a stop fixed at − 40° (the most convenient 'half shadow angle'); (5) adjust slit-width to give balance (6) rotate analyser clockwise through about 80° to position θ_2 to restore balance, then the zero i $\frac{1}{2}(\theta_2 - 40)$.

Readings of rotation are made in a similar way (1′) place cell with solution in light-beam; (2′) adjus transmission scale. If the solution is transparent the scale is left at 100 per cent; but if absorption i present it may be necessary to select a smaller valu to prevent the slit-width from becoming too larg

Operations (3′), (4′), (5′) and (6′) are then carried out as for (3), (4), (5) and (6). If in (6′) the analyser scale reads θ, the desired rotation α is given by

$$\alpha = \tfrac{1}{2}(\theta - 40) - \tfrac{1}{2}(\theta_0 - 40) = \tfrac{1}{2}(\theta - \theta_0).$$

The accompanying table contains values of rotation α and specific rotation [α] for various wave-lengths λ, obtained with a benzene solution of caryophyllene nitrosite (concentration 1·5280 gm. per 100 ml.) in a 1-cm. cell.

λ	α	[α]	ε
5000	+ 1·47*	+ 962*	0·30
5500	+ 1·98 *	+ 1293	1·38
5800	+ 2·40 *	+ 1571	2 53
6000	+ 2·67	+ 1748	6·17
6250	+ 2·74	+ 1794	10·50
6500	+ 2·42	+ 1584	15·40
6750	+ 0·94	+ 615	21·21
6800	+ 0·41	+ 268	21·99
6900	− 0·61	− 400	21·05
7000	− 1·96	− 1283	18·46
7250	− 3·05	− 1996	10·14
7350	− 3·07	− 2009	6·80
7500	− 2·82	− 1846	3·25
7750	− 1·84	− 1204	0·77
8000	− 1·30	− 851	—
8500	− 0·76	− 498	—
9000	− 0·49	− 303	—

* Visual readings.

It is seen that the specific rotation (column 3) passes through positive and negative maxima at about 6250 A. and 7350 A., respectively. Previous visual measurements had revealed only the positive maximum. Molecular extinction coefficients ε (also found with the Unicam spectrophotometer) are included in the table (column 4). Maximum absorption occurs near 6800 A. where [α] ≃ 0.

The analyser unit described above was constructed in our workshop under the direction of Mr. Robert McCulloch. One of us (J. V.) is indebted to the Department of Scientific and Industrial Research for a maintenance allowance.

Modification of Crystal Habit of Inorganic Salts with Dyes

THE publication of H. E. Buckley's "Crystal Growth"[1], with its chapters on modified crystals, is likely to stimulate interest in this field of research; he time is therefore opportune for this indication to be given of a conception of modification of crystal habit with dyes which, so far as it is at present capable of being tested, appears to explain many of the contradictions and inconsistencies previously confronting workers in this field.

Recent evidence points to the growth at finite ates of crystal faces being due to the spreading of layers from continuously renewed nuclei on the faces[2]. It is now suggested, from study of some forty cases of strong crystal-habit modifications of anhydrous norganic salts, including nitrates, sulphates and perchlorates in particular, that the incorporation, emporary or permanent, of dye molecules in one or more of the edge-faces of these layers is the usual means by which the growth of a crystal face is retarded by the presence of a dye in the solution[3,4]. Alternatively, the propagation of the nucleus could be affected in a similar manner[5].

The edge-planes of these spreading layers may conceivably be vicinal faces of high indices, or the ordinary low-order planes of high reticular density normally bounding the crystal, or something in between, according to their stage of growth. Consideration of many individual instances of very strong crystal-habit modifications suggests that in most cases the dye is incorporated into the edges of such spreading layers by virtue of there being suitable coincidence between the dye's polar groups and ionic sites in a particular edge-plane of the layer, so that the dye molecule can be incorporated in the edge-plane by virtue of its polar groups replacing the appropriate ions. The edge-plane involved will depend to some extent on the orientation of the polar substituent groups of the dye molecule; alternative edge-planes may thus be involved in bringing about crystal-habit modification on one particular face. The concept is virtually of a 'two-dimensional solid solution formation' at the growing edge of a layer. It is evident that a planar dye molecule will lie entirely in one crystal plane, and where the dye molecule preferentially fits or can only fit in one plane, then favourable conditions for the exhibition of pleochroism by the completed crystal exist, if all the dye molecules are not dislodged in the growth process.

In order that a dye may have strong crystal-habit modifying properties for a given salt, it should have the following properties. (1) Its solubility in the saturated saline solution should be high; this implies that an adequate number of solubilizing polar groups should be present. (2) The charge centres of the polar groups should coincide accurately with sites for similarly charged ions in a crystal plane; the greater the number of polar groups fitting into the lattice, the stronger the adhesion of the dye. (3) Any such polar group should not occasion disturbance of the lattice about the ionic site in question; any exclusion of adjacent ions will result in a diminution of the Coulomb forces responsible for the adhesion of the dye molecule. Hence arises the importance of a suitably close coincidence between the oxygen triangles of sulphonate groups and oxyacid ions.

Since presumably a certain amount of misfit may be tolerated in some cases at least, this conception of habit modification is quite consistent with the large number of dyes found by Buckley to have habit-modifying properties in various degrees. Further, it is evident that a certain selectivity will be exercised by the crystal structure, and not all dyes will fit; and that the effective dyes will depend on the crystal structure to be modified. Differing types of habit modification of one substance will depend on the different planes on which the dye molecules can fit.

Since commercial dyes are often complex, and erroneously described in the Colour Index, only strong habit modifications obtained with specially prepared pure dyes of known simple constitution have been considered. It has been possible to demonstrate by graphical methods that the requisite accurate coincidences between polar groups and ionic sites are, in fact, possible on planes indicated by the pleochroism of the dyed crystals as being the seat of the dye molecules, in such cases as the habit modification of ammonium nitrate IV with naphthol red *S*, acid magenta and 1 : 4 diamino anthraquinone 2-sodium sulphonate, for example. In certain cases, where the plane including the dye molecules is multiplied in the crystal by symmetry operations, and as a result the dye molecules are not parallel (for example, in the trigonal and hexagonal systems when modification is on the basal plane), pleochroism of dye inclusions in the modified crystals cannot be expected. Where it has not been possible to obtain crystals with pleochroic adsorbed dye inclusions, the necessary coincidences between the polar groups of dyes and ionic sites of suitable planes to account for the observed habit modifications may be similarly demonstrated. It is perhaps noteworthy that a small minority only of the habit modifications examined appear to be capable of explanation by fitting the dye molecule directly into the habit-modified face (for example, potassium nitrate with acid magenta). In these cases the habit modification is apparently not so strong as that found when the same dye fits on to a plane perpendicular to a habit-modified face of another salt; close comparisons are not justifiable, however, when solubility differences exist.

Some attempts are being made to predict the structures of crystal-habit modifiers according to this theory. In a certain number of cases success has been achieved; but a difficulty has arisen, that it is impossible to predict the solubility of the dye, which depends just as markedly on the orientation of the polar substituent groups as does its crystal-habit modifying powers[6]. A full account of this work will be reported elsewhere.

Contamination of Evaporated Films by the Supporting Material of the Source

IN studies of the properties of films produced by vacuum evaporation, it is important to know whether appreciable contamination by the material of the boat or filament occurs under the normal evaporation conditions. The mass of a film is usually very small, and some properties of films are very sensitive to minute amounts of contamination. A test of high sensitivity is therefore required. The radioactive tracer method possesses this necessary sensitivity when there is a suitable isotope of the material of the boat.

The mechanical properties of tantalum and its high melting point make it a suitable material for evaporation sources. It has an active isotope, tantalum-182, with a half-life of 117 days. Moreover, since the whole of natural tantalum consists of the 181 isotope, from which the active isotope is produced by neutron irradiation, a high specific activity is easily obtained. Experiments have been made with an active tantalum boat as evaporation source, the evaporated materials being tested for active tantalum in the usual way. Silver and germanium have been examined, the evaporation being carried out at several temperatures. One count per minute above background corresponds to $2 \cdot 3 \times 10^{-10}$ gm. tantalum in the deposit. The masses of silver and germanium deposited on the test target were of the order 10^{-4} gm., so that contamination to the extent of a few parts per million was detectable.

The results with germanium showed that the tantalum content of the film ranged from 11 p.p.m. for an evaporation temperature of 1,120° C. to 26 p.p.m. at 1,800° C. For silver, the figures recorded were from 20 p.p.m. at 1,100° C. to 113 p.p.m. at 1,670° C.

The mechanism by which the tantalum is transported is not clear, since the two obvious processes, namely, direct evaporation and solution by the molten metal, would be much more temperature-dependent. From the practical point of view, however, it is seen that provided the temperature of the source is kept below about 1,200° C., the contamination does not exceed 10–20 parts per million. As an indication of possible contamination when films are evaporated very rapidly, it should be stated that on one occasion the boat temperature was raised to above 2,000° C. and that the resulting film contained 1 part in 7 of tantalum.

Measurements of the Normal Stress Effect in Solutions of Poly*iso*butylene

Weissenberg[1-3], Garner and Nissan[4], and Garner Nissan and Wood[5] have described a number of ex periments which indicate that, in high-polymer solutions, steady-state laminar flow cannot be maintained by the action of shearing forces alone, even at low velocity gradients for which centrifugal effects ca be neglected. The effects observed in these experi ments have been interpreted by Rivlin[6,7] phenomeno logically as due to the fact that the relations connect ing the stress and strain velocity components for th steady-state laminar flow of such a solution involv a second physical parameter defining the flow pro perties of the fluid, in addition to the viscosity.

This parameter has been termed the 'normal stres coefficient', and effects which arise from its non vanishing have been called 'normal stress effects' From the phenomenological point of view, both th viscosity and the normal stress coefficient can depen on the state of flow through the flow invariants and if the flow is inhomogeneous, can vary from poin to point of the fluid.

It has further been shown[8] that values of the norma stress coefficient sufficient to give rise to effects c the observed order of magnitude could probabl occur in high-polymer solutions of a few per cen concentration as a result of the orientation of th dissolved molecules in the flowing solution.

The normal stress effect for solutions of polyiso butylene in *ortho*-dichlorobenzene has now been in vestigated using an experimental arrangement similar in principle, to one described by Weissenberg, an by Garner, Nissan and Wood. The solution is contained between two coaxial cylindrical cups as shown schematically in Fig. 1. The outer cu can be rotated at a variety of speeds and th distance between the disks forming the bases of th cups can be varied. The pressure which must b applied at these disks in order to maintain the solu tion in a steady state of laminar flow between them is measured automatically by a number of vertic tubes entering the base of the inner cup at variou

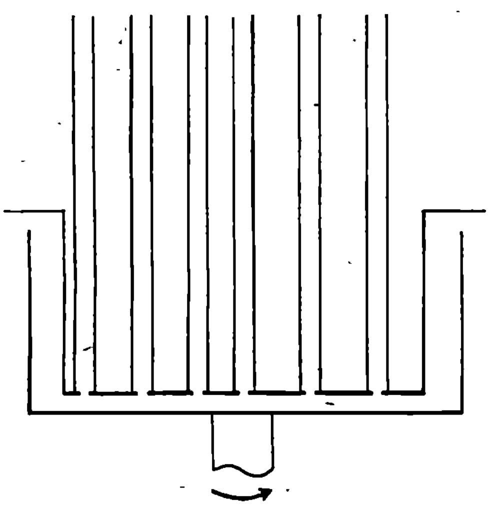

Fig. 1. Schematic diagram of apparatus

radial distances from the axis of rotation. The iquid is drawn up some way into the tubes, for ease of observation of its meniscus, by reducing the pressure n them, and the outer cup is rotated at constant speed. The change in level in each of the vertical tubes is then measured and is proportional to the normal surface traction applied to the plane surface of the fluid at the points of entry of the tubes.

Typical results, obtained with a 6 per cent solution of poly*iso*butylene (viscosity average molecular weight about 2 × 10^6) in *ortho*-dichlorobenzene, are shown n Fig. 2, in which the height of rise h of the solution n the tubes is plotted against their distance r from the axis of rotation for two different spacings of the disks d, that is, for two mean values of the velocity gradient. It is seen that the relations are substantially linear, small departures from linearity being obtained at low values of r for the higher value of d, and at high values of r for the lower values of d. The former departure from linearity increases and the latter decreases with decrease of the concentration of the solution and decrease of molecular weight of the polyisobutylene. It appears that for sufficiently low velocity gradients, concentration or molecular weight, substantial linearity between h and r^2 could be obtained.

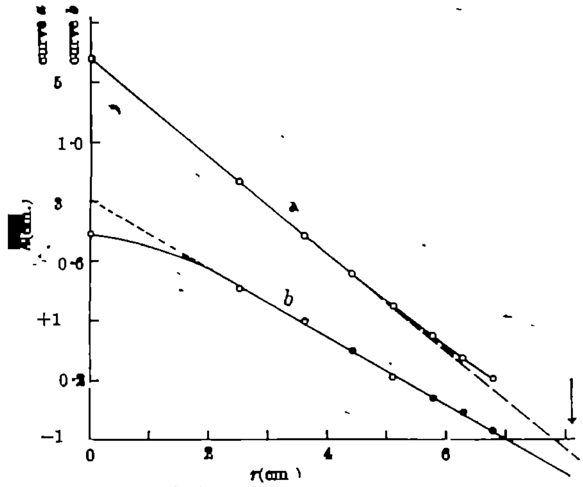

Fig. 2. Normal stress distribution over base of inner cup. h = height of rise of solution in tubes. r = distance of tube from axis of rotation. Curve a, disk separation, 0·12 cm.; speed of rotation, 40·9 r.p.m.; curve b, disk separation, 1·08 cm.; speed of rotation, 40·9 r.p.m. Arrow on right indicates edge of inner cup

According to the phenomenological theory advanced by Rivlin[6], h is related to r by the formula

$$\rho h = -\tfrac{1}{2}\Psi\frac{\Omega^2}{d^2}r^2 - \tfrac{1}{2}\frac{\Omega^2}{d^2}\int_a^r r\Psi dr, \qquad (1)$$

where ρ is the density of the solution, Ω is the speed of rotation in rad./sec., a is the radius of the cylinder and Ψ is the normal stress coefficient, which depends, in general, on a flow invariant $K_2 = -\tfrac{1}{2}\Omega^2r^2/d^2$. This result applies to the ideal case of laminar flow of a cylindrical body of fluid between plane disks, in which the curved surface of the fluid remains free. In the experimental arrangement used, the curved surface of the fluid is not free and therefore the absolute value of h, as distinct from its variation with r, will depend on the conditions prevailing at the edge of the disks.

Neglecting the small departures from a linear relationship between r and h found experimentally, we see that Ψ must be proportional to $(-K_2)^{-1/2}$ over most of the range of velocity gradients covered by the experiments, so that

$$\rho(h - h_0) = \alpha\frac{\Omega}{d}(a - 2r), \qquad (2)$$

where h_0 is a constant depending on the state of flow at the edge of the disks and α is given by $\Psi = \alpha(-K_2)^{-1/2}$. Mooney[9] has reported that results similar to (2) have been obtained by DeWitt with solutions of 'Vistanex' (poly*iso*butylene) in tetralin.

The particular relation between Ψ and K_2 leading to equation (2) is indicated by the linear relationship between r and h. It is seen that it implies a linear relationship between h and Ω/d. This has been verified experimentally.

Experiments carried out over the concentration-range 2·5–7·8 per cent showed that α is roughly proportional to the fourth power of the concentration. It has also been found that α decreases with increase of temperature. For example, for a 6 per cent solution, α decreased approximately linearly to about half its original value as the temperature was increased from 10° to 37° C.

A detailed account of the results obtained, together with the experimental precautions which were found necessary to ensure reproducibility and significance for the results, will be published later. A more critical discussion of their relationship to the various theories which have been advanced will then be given.

The work described in this communication forms part of a programme of fundamental research undertaken by the Board of the British Rubber Producers' Research Association and was carried out in the Davy Faraday Laboratory of the Royal Institution.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, October 15

UNIVERSITY OF LONDON (at the Institute of Neurology, National Hospital, Queen Square, London, W.C.1), at 5 p.m.—Dr. Donald Hunter: "Poisoning by Fluorine Compounds" (Guest Lecture).*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.15 p.m.—Sir Philip Manson-Bahr: "Patrick Manson, the Father of Tropical Medicine (his Pioneer Work and its Influence on Modern Advances)" (Manson Lecture).*

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE, PHILOSOPHY OF SCIENCE GROUP (in the Council Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. W. Kneale: "Observables and Unobservables".

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY (in the Reynolds Hall, College of Technology, Manchester), at 5.30 p.m.—Mr. H. Hayhurst: "Infestation in Stored Products" (Presidential Address).*

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 7 p.m.—Mr. K. C. Pounds: "Keeping Electricity Safe".

Tuesday, October 16

SOCIETY OF CHEMICAL INDUSTRY, AGRICULTURE GROUP (in the Chemistry Lecture Theatre, Royal College of Science, Imperial Institute Road, London, S.W.7), at 2.30 p.m.—Dr. E. W. Russell: "Soil Structure".*

INSTITUTE OF FUEL (at the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Prof. F. H. Garner: "Combustion Processes in Engines" (Melchett Lecture).*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.30 p.m.—Sir Jack Drummond, F.R.S.: "The Scientific Basis of Medicine, 3, Practical Aspects of Modern Nutritional Theories".* (Further Lectures on October 18, 23, 25 and 30, November 2, 5, 7, 14, 16, 20, 23, 27 and 29, December 4, 6 and 11.)

INSTITUTION OF ELECTRICAL ENGINEERS, EDUCATION DISCUSSION CIRCLE (at Savoy Place, Victoria Embankment, London, W.C.2), at 6 p.m.—Discussion on "The 'j' Operator Method of Calculation—When and How should it be Introduced?" (to be opened by Mr. A. W. Gillies).

TEXTILE INSTITUTE, SCOTTISH SECTION (joint meeting with the SCOTTISH SECTION of the INSTITUTION OF THE RUBBER INDUSTRY, at 25 Charlotte Square, Edinburgh), at 7.30 p.m.—Mr. G. Appleyard: "Textile Development in the Rubber Industry".

TEXTILE INSTITUTE, SCOTTISH SECTION (joint meeting with the INSTITUTION OF THE RUBBER INDUSTRY AND PLASTICS INSTITUTE, at the Royal Technical College, Glasgow), at 7.30 p.m.—Mr A. M. Dobson: "Glass Textiles as Reinforcement in the Rubber and Plastics Industries".

Wednesday, October 17

INSTITUTE OF METALS (at Park Lane Hotel, Piccadilly, London, W.1), at 10 a.m.—General Discussion on "Metal Economics".

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—William Smith Lecture.

UNIVERSITY OF LONDON (at the London School of Economics and Political Science, Houghton Street, Aldwych, London, W.C.2), at 5 p.m.—Prof. G. Friedmann: "Technological Change and Human Relations".* (Further Lecture on October 19.)

MANCHESTER STATISTICAL SOCIETY (at the Reform Club, King Street, Manchester), at 5.30 p.m.—Mr. J. Stafford. "Census of Production".

SOCIETY OF CHEMICAL INDUSTRY (joint meeting of the FOOD AND MICROBIOLOGY GROUPS with the LONDON AND SOUTH-EASTERN COUNTIES SECTION of the ROYAL INSTITUTE OF CHEMISTRY, at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Dr. J. R. Vickery. "Bacterial Wastage in Eggs and its Control".

Thursday, October 18

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. M. K. Wells: "Exploring the Roots of Extinct Volcanoes".*

INSTITUTION OF MINING AND METALLURGY (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific Papers.

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.30 p.m.—Sir Jack Drummond, F.R.S.. "The Scientific Basis of Medicine, 4, Practical Aspects of Modern Nutritional Theories".* (Further Lectures on October 23, 25 and 30, November 2, 5, 7, 14, 16, 20, 23, 27 and 29, December 4, 6 and 11.)

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at the Institution of Structural Engineers, 11 Upper Belgrave Street, London, S.W.1), at 6 p.m.—Dr. A. R. Lee and Mr. H. J. Dickinson: "The Durability of Tar and Tarmacadam".

CHEMICAL SOCIETY (joint meeting with the LOCAL SECTIONS of the ROYAL INSTITUTE OF CHEMISTRY and the SOCIETY OF CHEMICAL INDUSTRY, at The University, Manchester), at 6.30 p.m.—Prof. A. R. Ubbelohde, F.R.S.: "Some Problems in the Oxidation of Hydrocarbons".

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS, MICROCHEMISTRY GROUP (joint meeting with the LIVERPOOL AND NORTH-WESTERN SECTION of the ROYAL INSTITUTE OF CHEMISTRY, in the Chemistry Lecture Theatre, The University, Brownlow Street, Liverpool), at 7 p.m.—Discussion on "Chemical Microscopy".

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1, at 7.30 p.m.—Prof. C. A. Coulson, F.R.S.: "The Contributions c Wave Mechanics to Chemistry" (Tilden Lecture).

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at Manso House, 26 Portland Place, London, W.1), at 7.30 p.m.—Sir Ne Hamilton Fairley, F.R.S.: "Schistosomiasis and some of its Problems' (Presidential Address.)

Friday, October 19

ROYAL SANITARY INSTITUTE (in the Council Chamber, Town Hal Stockport), at 10 a.m.—Papers on "The Prevention and Control c Infectious Diseases".

BRITISH MYCOLOGICAL SOCIETY (in the Main Chemistry Lectur Theatre, Imperial College of Science and Technology, Imperial Institut Road, London, S.W.7), at 10.30 a.m.—Discussion on "Epidemiolog of Air-borne Fungus Diseases".

TEXTILE INSTITUTE, LANCASHIRE SECTION (at 16 St. Mary's Parson age, Manchester), at 1 p.m.—Sir Robert R. Hyde: "Changes an Developments in Industrial Relations".

BIOCHEMICAL SOCIETY (at the London Hospital Medical College London, E.1), at 2 p.m.—Scientific Papers.

ROYAL INSTITUTE OF PHILOSOPHY (at University Hall, 14 Gordo Square, London, W.C.1), at 5.15 p.m.—Prof. H. Dingle: "Science". (Further Lecture on October 26.)

INSTITUTION OF MECHANICAL ENGINEERS (at Storey's Gate, S James's Park, London, S.W.1), at 5.30 p.m.—Mr. A. C. Hartley Presidential Address.

MANCHESTER STATISTICAL SOCIETY, INDUSTRIAL STUDY GROU (at the Albert Hall, Peter Street, Manchester), at 6.45 p.m.—M P. J. Stanley: "Some Aspects of Production Statistics in the Aircra Industry".

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS PHYSICAL METHODS GROUP (joint meeting with the TEES-SIDE LOCA SECTION of the ROYAL INSTITUTE OF CHEMISTRY, at the William New ton School, Norton, Stockton-on-Tees), at 7 p.m.—Papers on "Physica Methods in the Pigment Industry".

Saturday, October 20

BOTANICAL SOCIETY OF THE BRITISH ISLES (at the Natural Histor Museum, Cromwell Road, London, S.W.7), at 2.30 p.m.—Exhibitio Meeting.

BRITISH PSYCHOLOGICAL SOCIETY (in the Eugenics Theatre, Un versity College, Gower Street, London, W.C.1), at 2.30 p.m.—Pro T. M. Newcomb: "Some Research on the Concept of Referen Groups".

INSTITUTION OF CHEMICAL ENGINEERS, NORTH-WESTERN BRANC (in the Reynolds Hall, College of Technology, Manchester), at 3 p.m —Sir Harold Hartley, F.R.S.. "Chemical Engineering and th Future".

LONDON COUNTY COUNCIL (at the Horniman Museum, London Roa Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. W. E. Swinton "100 Years of English Vertebrate Palæontology".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on o before the dates mentioned:

ASSISTANT LECTURERS FOR BIOLOGY AND CHEMISTRY—The Cle to the Governors, Essex Institute of Agriculture, Writtle, Chelmsfo (October 20).

GENERAL ASSISTANT ENGINEER (Mathematician), and a THIR ASSISTANT ENGINEER (Mathematician), in the research branch the Chief Engineer's Department in London—The Director of Esta lishments, British Electricity Authority, British Electricity Hou Great Portland Street, London, W.1, quoting Ref. No. AE/2 (October 20).

RESEARCH ASSISTANT to work on problems of applied econom forming part of the research programme of the Department Economics—The Registrar, University College, Hull (October 20).

SCIENTIFIC OFFICER (with a University degree in botany or ag cultural botany, with a sound knowledge of the principles of genet and practical plant breeding) IN THE PLANT BREEDING DIVISI of the Ministry of Agriculture—The Director of Establishmen Ministry of Finance, Stormont, Belfast (October 22).

STATISTICIAN (with thorough knowledge of statistical metho preferably in relation to social research) IN THE SOCIOLOGICAL RESEAR UNIT—The Secretary, London School of Economics and Politi Science, Houghton Street, Aldwych, London, W.C.2 (October 22).

RESEARCH FELLOW IN ECONOMICS OR ECONOMIC HISTORY at t East African Institute of Social Research, Makerere College (Univers College of East Africa)—The Secretary, Inter-University Council f Higher Education in the Colonies, 1 Gordon Square, London, W.C (October 25).

DEMONSTRATOR IN THE DEPARTMENT OF AIRCRAFT PROPULSION The Registrar, College of Aeronautics, Cranfield, Bletchley, Buc endorsed 'Demonstrator, Aircraft Propulsion' (October 27).

CHAIR OF ORGANIC CHEMISTRY at the University of Sydney—T Secretary, Association of Universities of the British Commonweal 5 Gordon Square, London, W.C.1 (November 12).

LECTURER (with a University degree or diploma, either in engine ing or in agriculture) IN AGRICULTURAL ENGINEERING at Canterbu Agricultural College (University of New Zealand)—The Secreta Association of Universities of the British Commonwealth, 5 Gord Square, London, W.C.1 (November 12).

AGRONOMIST IN THE DEPARTMENT OF AGRICULTURE, Gold Coast The Director of Recruitment (Colonial Service), Colonial Offi Sanctuary Buildings, Great Smith Street, London, S.W.1, quoti Ref. No. 27059/249.

CONTROL OF BROADCASTING IN BRITAIN

ALTHOUGH the dissolution of Parliament has made the Government's recent Memorandum* on the Report of the Broadcasting Committee of 1949 of somewhat academic interest, whatever government takes office will be required to deal with the broadcasting question as a matter of urgency. The present charter and licence of the British Broadcasting Corporation expire on December 31, 1951, and final decisions on future broadcasting policy cannot be postponed when next Parliament meets. It is apparent both from the Beveridge Committee's report and also from the debates in the House of Lords and in the House of Commons that division of opinion does not run on party lines. Nevertheless, it is vitally important that the significance of the real issues involved should not be lost to sight in the dust of political controversy, and that the decisions should be taken in the light of the fullest possible informed public discussion.

The criticism already expressed of the Report indicates that the debate on the monopoly issue is only just beginning, and that the Beveridge Committee was possibly too timid in considering alternatives to the present system. Because of the urgency of the question and the general trend of discussion, no government is now likely to feel able to do other than extend the present charter on much the same basis, as is proposed in the present Memorandum. In view of the discussion now proceeding on the monopoly issue, as well as the possible technical developments in television and the introduction of very-high-frequency broadcasting, the Memorandum was manifestly right in proposing to renew the charter for a limited period only. The fifteen years suggested seem a reasonable compromise, provided that due regard is had to the fact that certain of the changes recommended by the Beveridge Committee are likely to weaken the administration of the Corporation and, while avoiding abuse of monopoly, make the Corporation inefficient or at least less effective. Moreover, technical developments may offer more promising means of breaking the monopoly or minimizing its inherent dangers.

There are two particular points to be kept in mind. First, during the next fifteen years the danger of ossification in the Corporation is likely to increase. With the passage of time, various areas of B.B.C. activity will lose their novelty and the scope for new ideas will become progressively smaller while the influence of tradition increases. The development of the Home and Overseas Services and now of television cannot indefinitely supply the stimulus they have done during the past two decades. The recommendations of the Beveridge Committee on the administrative side may well accentuate this senescence. This risk requires fuller consideration than is given in the Memorandum.

The second point is that stressed by Prof. John Coatman in an article in the *Journal of Public*

---

* Broadcasting: Memorandum on the Report of the Broadcasting Committee, 1949. (Cmd. 8291.) Pp. 12. (London: H.M. Stationery Office, 1951.) 6d. net.

Administration (29, 160–172; 1951). Prof. Coatman points out that the British Broadcasting Corporation differs from most other public corporations in that its general policy cannot be clearly distinguished from the day-to-day activities which bring it into touch with the public and are the main occasion of criticism. The content of the programmes provokes the bulk of public criticism, and a structure of central responsibility which excludes or ignores such criticism of day-to-day policy is to that extent unreal and unadapted to the situation. To limit public discussion in Parliament in this respect is not in keeping with the nature of the public service which the Corporation provides and, in fact, sells.

Prof. Coatman seeks his solution in an administrative structure on the lines of that of a university. The prototype of the organization Prof. Coatman visualizes is the university with its senate and its council or court. Corresponding with the senate, he suggests, should be a body of high-ranking officials in the B.B.C. charged collectively with similar duties and responsibilities in regard to their work. Major projects such as the inauguration of the Third and Light Programmes, the creation of the board of management and like important matters would be fully discussed by this body, and the governors would be guided by its advice. It would supervise the programme output in respect of quality, technical competence, subject-matter and distribution of time, see to the proper co-ordination of the central and regional programmes, and at the same time eliminate one of the main weaknesses of the existing system, namely, excessive concentration of executive authority at the centre.

The board of governors would correspond with the university council or court, and its relations with the body proposed would be similar to those of the council or court with a university senate. Prof. Coatman suggests further that the board of governors might include a member of the 'senate'. The proposal would ultimately, he suggests, revolutionize the relations between Parliament and the B.B.C., would lighten the responsibility of the Government in respect of broadcasting and would make the B.B.C. a far more democratic and efficient instrument.

There are two conditions, however, which must be served if those purposes are to be achieved, especially if one stresses any analogy between the constitutional position of the B.B.C. and that of the universities in Britain. The first of these is that emphasized by Prof. Coatman himself. Really effective decentralization is essential. Besides broadcasting commissions for Scotland, Wales and Northern Ireland, there would be one or more for England, with functional devolution of television and overseas broadcasting. Really viable units of control would thus be obtained, the activities of which would be co-ordinated in the federal board of governors. Besides this, Prof. Coatman would make either the Lord President of the Council or the Lord Privy Seal responsible for acting for the Government in relation both to Parliament and the B.B.C., apart from matters which, under the Telecommunications Act, fall within the competence of the Postmaster-General. Parliament itself might also appoint an all-party broadcasting committee which would be responsible for keeping in touch with the broad policies and day-to-day activities of the Commissions and the federal B.B.C. board to see that the conditions of the charter are not violated and that the public interests in broadcasting are duly served.

The second condition is that any analogy between the constitutional position of the B.B.C. and that of a university must not be pressed too far. It is purely an administrative matter. The B.B.C. is not and could not be in any sense a university, despite the talk about the Third Programme being 'a university of the air'. Education is only one of the functions of broadcasting. Concern over the maintenance of standards or the elimination of administrative difficulties must not lead us to overlook the fact that the Corporation ultimately must provide what the listener requires. Safeguards against the lowering of standards must not be carried to the point of dictation.

There would appear to be room for much more constructive and fundamental thought on this question of the implications of monopoly and on the maintenance of standards than the recent Memorandum indicates. The first point, about viable units of control, has, however, not been included in the Memorandum. While attaching great importance to the maximum devolution to all areas in programme policy, and recognizing the need for the English regions as well as Scotland, Wales and Northern Ireland to have full opportunities of making their distinctive rich and diversified contribution to the pattern of British life and culture, the administrative implications are apparently not realized. The proposals of the Broadcasting Committee to appoint to the board of governors 'national' representatives, and that there should be 'national' bodies—for which the name 'Broadcasting Councils' is proposed—the primary function of which would be to control the general policy and content of their home programmes, are accepted. In regard to finance and capital development, such Councils would have advisory functions only; but they would be responsible for the appointment of staff wholly employed in connexion with their Home Services.

This is not federation, nor is it decentralization in the sense urged by Prof. Coatman. The idea of 'representation' on the board of governors is in itself objectionable; but the more serious aspect of the proposal in the Memorandum is that such 'national' representatives on the board of governors should themselves each be chairman, not of a commission of five, as suggested by the Beveridge Committee, but of an unpaid broadcasting council drawn mainly from nominees of the county councils and major urban local authorities. The Beveridge Committee did not propose any change in the English Regional Advisory Councils except to increase their independence and knowledge, and thus to strengthen existing programme autonomy of the regional controller; but the Committee recognized that it would be for the proposed national commissions to decide whether or not to appoint such advisory councils in their areas.

The immediate effect of the proposals of the Memorandum would clearly be, first, to destroy the authority of the regional controller and, secondly, to subject the regional programmes to political and sectional pressure. The bodies proposed could not but have a strong local-government and probably party-political trend, and local sectional interests would continually press on the regional controller. Quite rightly the governors of the British Broadcasting Corporation have pointed out that the proposal would for the first time introduce into British broadcasting a system of control into which a political element would be entering. Not only would this be a break with a principle which has been one of the strongest features of the B.B.C., but also it introduces a dual allegiance which itself is liable to endanger standards.

It would be fair to suggest that the Memorandum gives insufficient thought to what is implied by regionalism and to the distinction between separation and the federation advocated by Prof. Coatman. The governors' comment on the proposals indicates that there is real danger that the adoption of such proposals would lead to the fragmentation of British broadcasting and the disappearance of all national programmes. Fortunately, the Memorandum's proposals here, and particularly the selection of broadcasting councils from local authorities, found so little support in Parliament that it was intimated that final decisions would not be taken until Parliament had expressed its views; this should make it easy to drop the whole proposal for regional devolution.

It is to be hoped that the administrative aspect of the proposals will also receive further attention than was apparent in these two debates. While the potential clash of loyalties which might be involved for the B.B.C. staff in devolution was duly noted by several speakers, few apart from Capt. L. P. S. Orr and Mr. A. Wedgwood Benn indicated any appreciation of what was implied financially or administratively. Capt. Orr, quoting from the Beveridge Report that no region could afford by itself to provide a programme service in any way comparable with what is now being achieved by the combined effort of all, rejected devolution accordingly as meaningless without fiscal autonomy. Those who suggested separate corporations for Wales or Scotland did not attempt to meet the difficulty of the limited number of wavelengths available, which was put quite frankly by Mr. Gordon-Walker in opening the debate on July 19.

The problem of decentralization and of the excessive size of the present Corporation was most constructively handled by Mr. Wedgwood Benn, whose suggestion for four boards of management or corporations, responsible for overseas broadcasting, for television, for the Home Service and for the regions, went far towards meeting the need for viable units of control. This was the most constructive suggestion for dealing with this question advanced in either debate, but it is apparent that much more thought is still required in these matters of regionalization and administration before we can secure the steady progress towards greater decentralization, devolution and diversity put forward in the Beveridg Report. Moreover, whatever the immediate decisio as to the terms of the new charter, it is importan that the utmost care should be taken to ensure tha adequate encouragement is given to the developmen of new scientific methods and processes which migh greatly facilitate devolution and decentralization i future.

Mr. C. I. Orr-Ewing directed attention to th possibilities in this direction which the use of very high-frequency broadcasting may offer. Such possibilities are a matter of finance also, and this is on reason for deploring the Memorandum's proposal t raid the B.B.C. licence fund. It is proposed, with n reason except the ingenious argument that "i present circumstances the B.B.C. should make som contribution to the general revenue", that th Government should take 15 per cent of the net licenc revenue for the first three years of the new charte and that the position should be reconsidered at th end of that time.

This proposal also has brought a strong prote from the governors of the B.B.C., who point out tha since January 1, 1947, the B.B.C. has already contributed from its revenues £4,666,330 to meet incom tax, and that in the next ten years the prop development of the broadcasting service would ta the Corporation's resources so fully that, if remissio of income tax was not obtained, even though 100 p cent of the net licence income was retained, the Co poration would eventually face a deficit of £6,800,00 The Corporation will accordingly, if only 85 per ce of the licence fee is retained, be forced to borro money which the listener will have, in effect, alread contributed. The proposal was heavily attacked i both debates, alike from its effect on technica developments and from the point of view of i essential dishonesty, the implications of which hav already been noted in these columns.

There can now be no doubt as to the misgivin with which the proposals of the Memorandum a regarded on all sides, independent of party lines. no satisfactory scheme of devolution can be devise immediately, it is imperative that the utmost ca should be taken to strengthen the regional advisor councils and to promote means of bringing effectiv criticism to bear upon the hierarchy. Metho adopted for that purpose or to strengthen the positio of the governors and make them more effectiv watchdogs for democracy must not impair th administrative soundness of the organization, o encourage the danger of senescence to which it ma well be increasingly exposed. Further, there mus be the fullest possible resources available for th exploration of the new technical developments an their implications. It is to be hoped that whe official proposals are again forthcoming, they wi take fuller account of these matters, that the rai on the licence revenue will be dropped, as well a the threat of introducing political influence into th regional councils; and that whether the charter i renewed for fifteen years or a shorter period, ther will be ample opportunity for ensuring that not onl are new technical developments explored but als the means of averting the dangers inherent in a monopoly. Only by careful attention to such matters can we hope that British broadcasting will continue to uphold its high standards and tradition, and to reconcile its function of selling a public service with the maintenance of an unrivalled reputation for integrity and political impartiality.

SUPERCONDUCTIVE ELECTRODYNAMICS

Superfluids

Vol. 1: Macroscopic Theory of Superconductivity. By Fritz London. (Structure of Matter Series.) Pp. viii+161. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1950.) 40s. net.

ALMOST twenty years ago Dr. H. London—then a young research student at the University of Breslau—realized when dealing with the problem of a perfect conductor in an alternating magnetic field that Maxwell's equation $J = \sigma E$ becomes inadequate when $\sigma \rightarrow \infty$, since it makes no provision for the inertia of the electrons. Instead he proposed $\dot{J} = (1/\Lambda)E$, where Λ is a new constant which he called "internal specific self-inductance". He thus showed that a magnetic field will enter a superconductor and that the depth of penetration is determined by Λ. In the same year (1933), Becker, Heller and Sauter published a paper in which by considering the problem of a rotating superconductive sphere they arrived independently at the same result.

In 1934, H. London joined his brother, F. London, in Oxford, but in the meantime an important development had taken place—Meissner had discovered the expulsion of a magnetic field from the superconductor. A confused situation had arisen leading to vain attempts at relating the new phenomenon of zero induction with the known fact of zero resistance by means of ordinary electrodynamics. In 1935, F. and H. London provided this link by proposing the new equation, curl $\Lambda \dot{J} = -(1/c)H$, which in conjunction with the equation of H. London and Becker has since won general recognition as the fundamental law of superconductive electro-dynamics. In a number of papers F. and H. London have further extended the new electrodynamics, treating various aspects of the subject and providing great stimulus to experimental research. F. London, in particular, has elucidated the quantum-mechanical significance of the theory.

His new book is the first comprehensive summary of the work to be written in English. In 1937 he had written a rather shorter monograph in French[1], and another on the same subject, by M. von Laue, has more recently been published in German[2]. After introductory chapters on the magnetic phenomena and thermodynamics, the equations are introduced and applied to a number of problems. Then their significance is discussed in relation with the assumption of non-viscous flow. The determination of the penetration depth by measurements of the susceptibility and by microwave absorption is described. The next section, dealing with the intermediate state and domain structure, is followed by a discussion of the surface energy between the superconductive and the normal phase and of the transition of thin wires and films. The final section sets out a programme for the molecular theory of superconductivity, and contains the interesting conclusion that in the superconductor it is the momentum vector rather than the current which exhibits long-range order. It is this concept of momentum condensation on which the similarity with liquid helium II, stressed in the introduction, is based.

This clear and rigorous account of a difficult but fascinating subject will be greatly welcomed by all working on superconductivity. One could only wish that the author had been as careful when making historical statements as he has been with regard to the subject-matter. To say that Tisza's two-fluid model of liquid helium (1938) "was not taken seriously enough to be given an experimental test" which had to wait for Kapitza's work in 1941 is quite unjustified, since, in fact, such a test—which yielded a positive result—had been made in Oxford in 1939. The way in which the pioneer work of Becker and co-workers is introduced also does not do full justice to the achievement which it constituted at the time. The analogy between liquid helium and superconductivity has been suggested by others as well, and mention of their work would have detracted nothing from the author's own fundamental contribution. These are, however, very minor blemishes which do not affect the subject-matter of the book. It can certainly be recommended to any research student embarking on the theoretical or experimental study of low-temperature phenomena.

IMPACT OF SCIENCE ON FARMING

The New Farming

By Dr. D. H. Robinson. New edition. Pp. 234+16 plates. (London: Faber and Faber, Ltd., 1951.) 16s. net.

THE line between pure and applied science is getting more indistinct, and much of the new knowledge now being used to good effect on the farm is neither simple nor elementary from the scientific point of view. For example, the scouring of cattle on the so-called 'teart' pastures might easily have been ascribed to copper deficiency, and it must be confessed that there was an element of luck in the discovery that it is, in fact, caused by an excess of molybdenum. The solution of the problem presented by the warble fly, or the disentangling of the many sheep diseases, has required much purely scientific work of a very high order. Consequently, a smattering of the elements of a few sciences is no longer sufficient for the agriculturist; he is faced with the task of keeping up with new advances in a number of fields of scientific endeavour.

Dr. D. H. Robinson has set out to simplify this task, and in a little more than two hundred pages he exemplifies the benefits that farming has received from new knowledge. The tale is not, of course, complete. The wider matters of economics and farm management are outside the scope of the book, and in each chapter the method is to pick out the more prominent cases where science has been successful by way of illustration, rather than to cover the subject completely. The examples are skilfully chosen, however, and together they give a good picture of the impact of science on modern farming, stressing the large contribution that has already been made and indicating the exciting quests which still remain.

It is doubtful if the book would provide a very digestible meal for the non-technical reader; it is very concentrated, and there is no room for explanation of all the terms used. To the agriculturist and to the farmer (in common parlance these two words are not synonymous) it offers a real feast. The chapters on the soil and on crops are sound and satisfying (except for a misprint in regard to the production of sugar in Great Britain), while that on grassland is absorbingly interesting; pests and diseases of crops and livestock, the breeding and feeding of farm animals, herbicides and ensilage are ably discussed. The reviewer started reading the book with some scepticism, doubting whether in such a small compass enough could be included to be useful with sufficient description to make it intelligible. But there is no denying that the aim has been achieved and the reader's interest is held, though that of one reader flagged somewhat over the work of the engineers.

This is not a text-book, although it contains much information. It brings the reader up to date on many questions, impresses on him the importance of science in agriculture and stimulates him to ask for more. It is certainly very easy to read because the English is simple and clear, with a nice economy in words.

THE NEW FOREMANSHIP

The Foreman

A Study of Supervision in British Industry. Undertaken by the National Institute of Industrial Psychology and sponsored by the Human Factors Panel of the Committee on Industrial Productivity. Pp. 158. (London and New York: Staples Press, Ltd., 1951.) 12*s*. 6*d*. net.

As Sir George Schuster says in the foreword, this book deserves notice for three main reasons. First, it is a study of a subject the importance of which is recognized by all who are concerned with the pressing need to increase Britain's industrial productivity. Secondly, the method of investigation —the collection of facts before the elaboration of theories or opinions—is one which is relatively unknown in those sectors of Britain's industrial life which determine the behaviour of men and women. The third merit of the book is that it is one of the projects sponsored by the Human Factors Panel of the Government Committee on Industrial Productivity. It is, in fact, the first comprehensive report to be published on any of these projects, and its contents and presentation augur well for those on joint consultation and other aspects of human relations in industry which are yet to come.

The contents of the book are partly based upon information collected by six investigators over a period of two years. During this time 107 factories were visited, and individual studies of 752 supervisors and their jobs were completed; the report relates to information collected from 87 of the factories and all the individual supervisors. During these investigations a questionnaire covering various aspects of foremanship was sent to some 4,700 establishments employing more than 250 persons, of which 751 returned completed forms. The investigators also devised and carried out trial selection procedures and training courses as well as collaborating with others who were responsible for similar courses. Visits were made to a number of supervisory training courses within firms, in technical colleges and training institutions in Britain and other European countries. In addition, the activities of various foremen's associations, discussion groups and related organizations were observed, while the investigators also made an extensive study of the British and foreign bibliography on foremanship.

It may thus be fairly claimed that the survey has been comprehensive and thorough. But the investigators have not been misled into thinking that their observations have been complete or made into typical cross-sections of British industry. It proved impossible, for example, to arrange for a random sample of firms to be studied, and many of the factories visited were probably above average in several aspects of management policy and practice. Similarly, the foremen seen in each firm probably included too high a proportion of the more able men. For these reasons the investigators readily admit that, almost certainly, the study presents too favourable a picture of existing practice in British industry.

Yet the conclusions will not be without value if they do no more than stimulate discussion on an important subject. They confirm the common belief among thoughtful managers that foremanship to-day requires different skills from those needed in the past; the power of being able to 'sack' has given way to the need for positive leadership based on knowledge, ability and personal qualities. The modern foreman is closely concerned with questions of human relations and administration as well as with his technical and production responsibilities. He must be selected for his capacity to gain the respect, confidence and co-operation of his operatives, colleagues and managers, and he must be trained so that these potentialities will be fulfilled.

Apart from the statistical analyses, much of this book is devoted to the views of the investigators on the status of the supervisor and ways in which he should be selected and trained. Their occupational analysis of supervisory work (on pp. 32–34) is one of the most valuable features of the book, although their prescriptions for selection and training may need revision as further diagnoses are made. In this connexion one of the most practical suggestions put forward by the investigators is the need for a residential centre for supervisory training. For small and medium-sized firms, particularly, such a centre would be of incalculable worth, and it is to be hoped that the sponsors of this investigation will make the necessary approach to industrial and educational organizations and the government departments concerned; a junior version of the administrative staff college is overdue.

The presentation of this survey leaves little to be desired. It is always concise and usually clear; occasionally there is evidence of the efforts of several writers not all of whom have the same gifts for writing or clear thinking. The summaries at the end of each chapter are brief and to the point; the 'review and summary' at the end of the book has been shrewdly prepared so that readers may not forget that the evidence collected and the views put forward by the investigators represent one of the most valuable statements yet prepared on the means of promoting good human relations in British industry.

T. H. Hawkins

ARCHÆOLOGICAL DATING OF THE CLIMATIC CHANGE IN NORTH EUROPE ABOUT A.D. 1300*

By Dr. AXEL STEENSBERG

National Museum, Copenhagen

It is a general feature of the agrarian history of northern Europe during the Middle Ages that large-scale colonization of land came to an end late in the thirteenth century, and that in the next two centuries it was followed by the abandonment of hundreds of villages in nearly all parts of north European countries. This phenomenon seems to be connected with a climatic change, and in order to examine the problem briefly it is convenient to separate the sources roughly into two groups: on one hand, the literary records and, on the other, what may be called the scientific evidence.

Among the literary sources one may first mention the hundreds or thousands of notes about the weather of whole years, of seasons or of single days which medieval annalists have included in their historical records. This information has never been studied properly in the full light of modern textual criticism, or with regard to the misconceptions upon which some of them were based. For medieval Denmark, including the lost provinces of Skåne and Holstein, such notes about weather were collected by a doctor of medicine, F. V. Mansa, nearly a hundred years ago[1]. Such data have also been published in the *Scriptores Minores* and *Annales Danici*. For Germany, similar information has been collected by Fritz Curshmann for the period up to 1317[2] and by R. Hennig up to 1800[3]. For Iceland the material has been collected by Dr. S. Thorarinsson, of Reykjavík, and others.

I do not think myself that it is possible to draw any exact scientific conclusions from such imprecise material. The difficulty is, of course, that the records are subjective, and what we find in the annals is almost entirely confined to relative statements. Some few of the official Danish documents do, however, give some information of scientific value which is particularly relevant to this problem. In 1334 they record for the first time that a farm has been left desolate. During the next three or four hundred years this became a general phenomenon in Denmark. The Danish Place-Name Society has recorded the names of hundreds of villages abandoned during the late Middle Ages. They nearly all seem to be names of the type with the termination *-thorp*. In Denmark most of the villages with names terminating in *-thorp* were founded in the early Middle Ages, that is to say, from the tenth to the twelfth century. In one small district of Jutland there are to-day eighteen villages with this name-ending; the Place-Name Society knows of sixteen other *-thorp* villages in this district which were abandoned in the late Middle Ages, and, of course, there may have existed others the names of which have been forgotten.

For Zealand the archivist Svend Aakjær has just published in the *Danish Historical Review* tables which show the decrease in the area of cultivated land from about the middle of the thirteenth until the late fourteenth century. Broadly speaking, the parish tithes of seventy-nine parishes in Zealand declined by about 70 per cent. This retraction of the cultivated land in the late Middle Ages is also well known in England. In 1943 the German scholar W. Abel published his "Die Wüstungen des ausgehenden Mittelalters"[4]. Prof. J. Schreiner, of Norway, has shown that the retraction was a general phenomenon throughout northern Europe[5], whereas we know from other sources that the agriculture of Italy was flourishing in the fifteenth century. Everywhere in northern Europe the retraction was connected with a fall in the prices of corn and with a falling population. Prof. Schreiner has shown clearly that corn prices fell from about 1300, whereas it was not until 1348 that the pestilence known as the Black Death first broke out. The English records of the output of corn from year to year, which are preserved for some abbeys and manors throughout the Middle Ages, do not show any decline of output starting anywhere around 1300, but this may be due to the fact that all the land to which the English records relate had been tilled and cultivated intensively from Saxon times or even longer. Such well-tilled land with a big content of humus is not very sensitive to an increase in the wetness of the climate. A change from less to more rainfall would first hit marginal lands recently brought into cultivation, which commonly lack humus in their raw clay and sands and which are therefore the first to be affected by climatic changes.

All this, however, only shows that there is nothing inconsistent between an unchanged record of corn output and a climatic deterioration. It does not prove that such a change occurred; and, indeed, the historical sources clearly cannot themselves provide any such proof.

Recently Dr. S. Thorarinsson, in his work "Tefrokronologiska Studier", has tried to date the layers of ash from the volcanoes of Iceland, and seems to have been completely successful[6]. It has been possible to fix the layers of the big eruption of Hekla to the year 1300. It seems clear that in Iceland a climatic change at about this time brought corn-growing to a gradual end. Pollen analysis has shown that corn-growing started in Iceland when settlers occupied the country in the Viking period; in particular, they grew barley and also some oats. Corn-growing had not quite stopped in the year 1300 when Hekla had its great eruption, the ashes of which can be discerned in the bog strata. It cannot be argued that corn-growing stopped merely because importation became easier as a result of trading with the Hanseatic League in the late Middle Ages, for, until modern times, Iceland never had better intercourse with foreign countries than during the tenth century, when corn-growing reached its maximum. Dr. Thorarinsson has also shown that the glaciers of Iceland advanced from the late Middle Ages until they reached a maximum about the year 1700. Since 1850 they have been retreating again, and it is now again possible to grow some corn in the country.

Franz Firbas and others have investigated the history of the vegetation in the Alps of Central Europe. In his "Untersuchungen über die Entstehung der heutigen Waldstufen in den Sudeten" (1949) he mentions that woods with abundant beech trees covered the Riesengebirge right up to the ridges of the mountains at least until the beginning of the fourteenth century[7]. From the fourteenth to the seventeenth centuries the upper tree-line lay 100–200 m. lower than either before or after. In the western Alps also, the glaciers advanced from about 1300 onwards, but they retreated again during the fifteenth century; a new advance began about 1600. When, however, Brooks in his "Climate through the Ages" correlates these changes with the climatic history of Iceland, he is probably making a mistake. Thorarinsson mentions that in Iceland there was also a glacial advance in the sixteenth century and beyond, lasting until the mid-seventeenth century or even into the mid-eighteenth century.

---

* Substance of a paper read on August 14 at Edinburgh before Section H (Anthropology and Archæology) of the British Association.

Before going on to discuss recent Danish investigations, mention must be made of the underground water which seems to have caused great difficulties in the silver mines of Central Europe in the years after 1300. The production of silver fell throughout Europe and caused a great shortage in England as well as in other countries. Of the Goslar mines in Germany, it is stated that in 1360 the water in the mines had been increasing for more than fifty years and that all attempts to improve the conditions had been in vain. Just after 1400 it is recorded that a new but unsuccessful attempt was made to resume production at the Rammelsberg mines. In Freiberg an attempt was made in 1365 to introduce a hoisting apparatus for getting rid of water, and a further unsuccessful attempt was made in 1379. In Bohemia the same problems arose in 1315 at Iglau, and the mines of Dutchbrod were abandoned as early as 1321. At Kuttenberg the use of mechanical drainage was started in the second half of the fourteenth century; but it was not until the Fugger merchants made extensive investments in the mines and in mining equipment in the late fifteenth century that silver production of Central Europe overcame the difficulty of excessive water[8]. These difficulties with water in the mines, starting as they do soon after 1300, provide a practical demonstration of the climatic change implied by the advance of the glaciers.

The best proofs of the reality of the change, however, will, I think, be found in the bogs and in the desolated villages of northern Europe. The Swedish pollen-analysis expert, Erik Granlund, published in 1931 his first observations on the so-called recurrence-surface No. 1 (the *RY* I), which he dated roughly to about A.D. 1200[9]. These recurrence surfaces represent renewals of the growth of sphagnum in the bogs concerned, and like the well-known *Grenshorisont* (designated *RY* III in Granlund's terminology) probably represent a relative increase of atmospheric wetness compared with the period which the surface terminates.

In 1943 Valdemar Mikkelsen, of Copenhagen, demonstrated the existence of such recurrence surfaces in five Jutland bogs, and in his work on Præstø Fiord in 1949 he advanced the thesis that the climatic change at *RY* I is characterized by the rise of the beech curve in the pollen diagrams and by the occurrence of *Centaurea cyanus*, the cornflower[9]. Cornflowers had not been identified in Denmark since the Late Glacial Period apart from one or two dubious finds from the Iron Ages. But from *RY* I Mikkelsen has now counted nearly forty grains. This is an exceptionally large number because the pollen grains of *cyanus* are spread only by the aid of bees and other insects, not by the wind, as in the case of a great many other pollen grains.

Dr. Hagbart Jonassen has also recorded the existence of the *RY* I[10]. In some diagrams of Jutland bogs which have been published in his work "Recent Pollen Sedimentation and Jutland Heath Diagrams" (1950), in each case the beech curve is rising just at *RY* I, but he has not noticed *Centaurea cyanus* because the sections which he has investigated lie in uncultivated areas in the Jutish heaths. Prof. Knud Jessen, in his work on the Late Quaternary deposits and flora history of Ireland published in 1949, states that there are similar recurrence surfaces in that country. So far, however, it has not been possible to assign exact dates to these surfaces. Even Granlund's date of about 1200 for *RY* I is very vague and problematical.

Dr. Mikkelsen and I think that we can now date *RY* I more exactly. I happened to carry out an excavation in an abandoned village named Bolle, in Vendsyssel, the northern promontory of Jutland. This village was not one which had been abandoned in the Middle Ages but had survived until 1650, when it was abandoned in order to create a manor. The most interesting archæological discovery was the dam of a water-mill dated at the turn of the last century B.C. and the first A.D. I was excavating this site with interruptions during 1939–48. During the last season Dr. Mikkelsen and I carried out large-scale investigations into the stratigraphy and pollen distribution of the site.

The mill-pond was not, of course, made in a sphagnum bog, and it was therefore impossible to find the *RY* I itself. We did, however, find the fluctuations of the beech curve which we knew from so many other localities both in Jutland and on Zealand, and moreover the *Centaurea cyanus* started just where the beech curve was rising for the last time.

It was, however, the dating of this phenomenon which we wanted to know. Fortunately, during one of the first years of my excavation at Bolle, I happened to find a hearth on which iron ore had been reduced to iron, and among the layers of charcoal and slag I found some potsherds which could be dated with certainty to not earlier than 1250 and not later than 1325–50. I had been cautious enough only to destroy one-half of this hearth, and I remembered that it had been stratified with peat both above and beneath it; we therefore dug a section from the hearth out into the middle of the bog and took pollen samples from both ends. Dr. Mikkelsen was not able to let me have the pollen spectra and his commentaries at the time of writing this article; but he is just finishing his report, and this will appear within a year in publications of the National Museum. It will show that the bog at Bolle was dry from about the Viking period or the very early Middle Ages just up to the time of the dated finds, which can now be assigned to about A.D. 1300. It is exactly at this level that the *Centaurea cyanus* starts and the beech curve rises.

One naturally seeks for an explanation of these two characteristics. The increase of beech pollen need not indicate that the beech forest has actually been recovering because the climate has become wetter. Dr. Johannes Iversen has suggested that the increase may be no more than a relative one, expressing the fact that other tree species, the pollen of which were formerly represented in the bog, had by this time disappeared.

The phenomenon of the appearance of the cornflower is connected in some way with the cultivation of ordinary wheat. Nowadays the cornflower flourishes chiefly in wheat fields which have suffered much from winter frost. As yet, we do not know much about the kinds of wheat grown in Denmark during the Middle Ages. Mr. Hans Helbæk has studied grain impressions on potsherds and carbonized cereals in England, Ireland, Holland and Denmark, and he is now working on the rich Swedish material from Vallhagar in Gotland. In his book on grain impressions from English potsherds, published by the Royal Danish Society of Science in 1944, he and Prof. Jessen state that most of what popularly is called wheat from earlier periods in England is in reality naked or hulled barley, emmer (that is, *Triticum dicoccum*) or small spelt (*Triticum monococcum*)[11].

Ten years ago, when I was excavating some farm-sites in the village of Hejninge, near Slagelse in Zealand, I happened to find a heap of carbonized grain on a floor which could be dated by coins to between A.D. 1300 and 1500. Last year, when I was excavating the medieval levels of some farm-houses in Store Valby, also near Slagelse, I happened to find in a post hole some carbonized barley with a small piece of rye bread. This post hole had been covered by a fireplace layer within which was a coin, by means of which the grain and the bread could be dated to not later than about 1400, and potsherds in the floor to which the post hole belonged indicated a date for the finds of not much earlier than 1300.

This find led me to investigate every spot of black earth containing any sort of carbonized material which could be dated by means of potsherds or coins. I took Mr. Helbæk down to the site, and immediately he discovered single grains and seeds in other black spots. After this I took all this material back to the laboratory. Mr. Helbæk made a washing device to make it easy to divide the grains and seeds from the earth and dust, and he has made a number of interesting new finds which he expects to publish. Mr. Helbæk and I hope that it will soon be possible to reconstruct a generalized sequence of plants and seeds for the Middle Ages as it has already been possible to do for the prehistoric times. It will remain, however, very important that sites of villages which have been abandoned in the late Middle Ages should be excavated so that information on the mixture of corn and wild seeds in such places may be obtained. I am at present surveying the fields of such a village in Zealand, and I shall try to find the site by means of analysis of the phosphoric acid content. I am sure that the knowledge gained from such investigations, together with advances in the other fields of inquiry which I have mentioned, will yield much more exact information than has been available hitherto about the true character of the climatic change which we can be certain took place round about A.D. 1300.

THE EAST AFRICAN AGRICULTURE AND FORESTRY RESEARCH ORGANIZATION

By Dr B. A. KEEN, F.R.S.
Director

THE headquarters and laboratories of the East African Agriculture and Forestry Research Organization at Kikuyu, Kenya, formally opened by the Right Hon. James Griffiths, Secretary of State for the Colonies, during his recent visit to East Africa, were built with money provided from the research allocation of the funds made available by the Colonial Development and Welfare Acts. Although neither the initiation nor the stimulation of research into Colonial problems are new ideas in British Colonial policy—the work of the Imperial Institute and of the short-lived Empire Marketing Board affords evidence of this—the idea of regional research organizations serving a group of contiguous Colonies is a relatively new conception. The British Colonies lend themselves to this idea, forming such obvious groups as Malaya, West, East, and Central Africa, and the West Indies. The Colonies within a group have many common problems, and it is obviously more efficient and more economical of men and money to conduct on a regional basis the researches required.

The machinery for regional research into agricultural problems of both arable and animal husbandry has so far been most fully developed in East Africa. Although still short of staff, and handicapped by swiftly rising costs, the East African Agriculture and Forestry Research Organization is now functioning in its new headquarters and laboratories at Muguga near Nairobi. A sister organization, the East African Veterinary Research Organization, will share some of these new facilities, and is also in process of developing others for research into animal diseases on an adjoining site. The initial development of the Agriculture and Forestry Research Organization was greatly helped because it absorbed the staff of the East African Agricultural Research Institute established in 1927 at Amani in Tanganyika Territory, and certain new appointments could be housed there pending the completion of the new centre at Muguga.

The Colonial Development and Welfare scheme setting up the Agriculture and Forestry Research Organization was approved in February 1948. It was based on the conclusions of two East African conferences, held in 1946 and 1947, and on the recommendations of the director of the Organization, who had been appointed earlier in 1947, so that he could go into the matter on the spot. Two subsidiary schemes, one for the study of fertilizer responses in East Africa, and the other for the study of the serious 'sudden-death' and 'die-back' diseases of cloves in Zanzibar, were also set up earlier on grounds of urgency; the scientific staff for these was drawn from Amani, and the Agriculture and Forestry Research Organization scheme was designed to re-absorb them on the expiry of the subsidiary schemes.

Amani was quite unsuitable for development because of its isolation and very steep slopes; nevertheless, the decision to build near Nairobi, because of its central position and accessibility, would have been a costly one, but for the generous action of the Kenya Government in presenting an admirable site of 1,600 acres in the Muguga Forest Reserve, close to Nairobi and accessible in all weathers.

The Colonial Development and Welfare scheme for the Organization is based on a research staff of forty-five at the end of 1957; the intention was to reach thirty-five by the end of 1952, plus the appropriate administrative and scientific-assistant posts. Steeply rising costs have imposed changes in the original scheme. Thus, although the capital expenditure has been increased over the original amount, it cannot provide all the house and hostel accommodation needed, even for the scientific and administrative staff envisaged at the end of 1952. The buildings for administration, and for various common services that are discussed later, will serve adequately for the full original scheme; the laboratory accommodation is, however, insufficient for this, even allowing for some overcrowding. Rising costs have also affected the recurrent part of the scheme, and it will be very difficult to sustain even the establishment of thirty-five research officers; this number has been agreed on as the minimum required for a properly balanced research programme.

Headquarters building of the East African Agriculture and Forestry Research Organization

The capital grant was £296,000, and was wholly provided by the British Government. One-half of the recurrent costs is also provided from home, and the remaining half is shared in equal proportions by Kenya, Tanganyika and Uganda; Zanzibar also provides a small contribution. The budget for 1951 was about £80,000, so the share of any one territory was less than £14,000.

More than 54 per cent of the capital grant of £296,000 had to be spent on housing and site development items, such as access roads, boreholes, sewage and drainage; in Britain, the great bulk of the cost of these items would not have been incurred. The direct capital expenditure on the Research Organization was as follows:

Laboratories	£34,800
Library	13,000
Administration and offices	21,100
Site works for above	4,700
Workshops and stores	5,200
Equipment	42,800
Animal husbandry (under construction)	14,800
	£134,900

A considerable part of this capital expenditure has been incurred not for the Agriculture and Forestry Research Organization, but for the East African Veterinary Research Organization, in accordance with the declared policy of effecting the closest integration of these two research organizations in all matters of common interest. Thus, there is a joint Division of Animal Husbandry; the library, workshop and services will be common; the General Analysis and the Statistical Sections, although staffed by the Agriculture and Forestry Research Organization, will serve both organizations; one-quarter of the laboratories are for the use of the Veterinary Research Organization; and the administrative offices of both organizations are under the same roof. The administration block also includes, besides offices, the following items: Bureau for Epizootic Diseases; Forestry Bureau; librarian's room, book-binding and library service room, and stack room; rooms for the head of the joint Animal Husbandry Division; the Statistical Section of the Agriculture and Forestry Research Organization; and, finally, a large conference room and ante-room. The laboratories are in three single-story blocks, and there is ample space on the axial line of each block for the orderly placing of auxiliary buildings such as pot-culture and green-houses. Each block consists of six laboratories, 15 ft. × 20 ft., on one side of the corridor; on the other side there are six ancillary laboratories, each 15 ft. × 12 ft., a number of which are subdivided into rooms 7½ ft. × 12 ft., which is a convenient size for balance, washing-up, photographic rooms, etc. The possibility of future re-arrangement was borne in mind, and the laboratory blocks were so designed that none of the transverse walls is weight-bearing. Bench design follows modern practice, with bench legs and laboratory fittings in steel and of unit-design. Substantial economies over the cost of imported bench tops were made by constructing them locally from Mvule (*Chlorophora excelsa*) obtained from the Amani plantations, and by making floor-blocks from the waste pieces. The windows are of plate-glass louvres which provide adjustable ventilation and avoid the casting of inconvenient shadows from window-bars. As the station is nearly on the equator the axial line of the laboratories runs east to west, and further shielding from direct sunlight at varying seasons and times of day is provided by horizontal hoods projecting beyond the windows, and vertical fins between them.

The library has a 6,000-ft. run of shelves, with a maximum shelf height of 7 ft., so that no book is beyond arm's reach. Four study-cubicles have also been provided for the use of those writing reports or theses.

The research programme of the East African Agriculture and Forestry Research Organization, although at present incomplete because of staff shortages, is being worked out in close consultation with the territorial departments and the Colonial Office, so that the regional and Colonial Empire aspects, respectively, are kept under review.

The building-up of the regional programme offers some problems in co-ordination. The specialist officers of agriculture and veterinary services in the territorial departments, and in the 'commodity stations' such as those for coffee and sisal, are already following certain lines of investigation. In addition, there are the research centres of the Empire Cotton Growing Corporation at Namulonge in Uganda, the Overseas Food Corporation in Tanganyika and the recently established Tea Research Institute at Kericho in Kenya.

It is obviously to the general interest that each of these organizations should, when drawing up its own programme, be fully aware of what the others have in mind, and that there should be every opportunity for discussions, especially between those engaged on similar lines of work in different centres. It is, or should be, equally obvious that, in the laudable attempt to secure 'co-ordination of effort and prevention of overlapping'—to use a heavily over-worked phrase—there is much danger of elaborating the administrative organization at the expense of flexibility and freedom of the scientific work. This tendency is likely to arise in regions such as East Africa, where each Colony has its own departments of agriculture, veterinary services and forestry, and where the regional research organizations come under the East Africa High Commission; it may lead, for example, to a particular scientific committee being three or four times larger than necessary or, alternatively, to the formation of three committees where one would serve, plus yet a fourth committee to 'co-ordinate' the other three.

For these reasons every effort is being made in East Africa to develop horizontal contacts (direct communication on scientific matters between opposite numbers) instead of the usual vertical system employed for administration purposes. The arrangements outlined below are tentative and will, no doubt, be improved with experience. The East Africa High Commission has created an Advisory Council for Agriculture, Animal Industry and Forestry, composed of government, technical and unofficial representatives from each Colony, with the directors of the Agriculture and Forestry and Veterinary Research Organizations, and the other non-government research centres already mentioned. This provides a forum for the general discussion of agricultural problems both scientific and practical. The Council is forming an increasing number of specialist committees on specific scientific problems, such as plant breeding, soil survey, insecticides. Their membership consists of a small number of the appropriate research and specialist officers from the research organizations and centres, and from the territories. They review the existing work in their subject and make suggestions for co-ordinating and extending it. They have scientific functions only, with no executive or administrative powers. These latter, and their financial implications, are exercised by the directors of the two Research Organizations and the directors of the territorial departments of agriculture, etc.; here, co-ordination is obviously necessary, and it is achieved by sub-committees consisting of the three directors of agriculture (or veterinary services, or forestry) with the director of the Agriculture and Forestry Research Organization or the Veterinary Research Organization as chairman. For matters such as animal husbandry, the agriculture and veterinary sub-committees meet together. Because these sub-committees have administrative and financial responsibilities they are not responsible to the Advisory Council but to another body, the Research Organization's Committee. This Committee can be regarded as an embryonic governing body for the Agriculture and Forestry Research Organization and the Veterinary Research Organization. It has a small membership: the Members for Agriculture of Kenya and Tanganyika, with a government official from Uganda, which does not have the Member system; one non-official from each territory who is a member of the Central Legislative Assembly of the East Africa High Commission; the directors of the two Research Organizations, and one High Commission officer, with the Administrator—the chief executive officer of the High Commission—as chairman.

It is hoped that, by these means, there will be quick and effective decisions on the scientific aspects of programmes of work, and on the executive and financial aspects as well.

There is one generalization that has guided the developments just described. This is the recognition of the fact that, in general, the sequence between discovery and introduction to practice falls into three phases: first, basic or fundamental research that discloses a new fact or a general principle; second, technological investigations, consisting of a series of systematic experiments to see how the new knowledge is affected by the range of variation within the regional environment; third, the introduction of the results of the second phase into practice. The regional research organizations are, normally, responsible for the first phase, and the territorial departments for the third phase. But both are equally concerned in the second phase, and it is here that effective and economical team-work is achieved between the Research Organizations and the territorial departments.

UNSTABLE PLANETARY CONFIGURATIONS

By Dr. W. H. RAMSEY

Physical Laboratories, University of Manchester

THE present article describes a new type of planetary instability which arises in connexion with the theory of the internal structure of the earth which I have developed[1]. I attribute the sharp core discontinuity at about half-way to the centre of the earth, at which the density almost doubles[2], to a phase transition under pressure. This is in contrast to the older view that the core is iron which has separated under gravity from the less dense silicates of the surrounding mantle. In the new theory, the enormous pressure of 1·4 million atmospheres at the boundary of the core is presumed to have partially destroyed the molecular structure of olivine, the principal constituent of the mantle. The olivine in the mantle has the familiar ionic structure; in the core it is in a dense metallic state. In an ordinary polymorphic transition, in which the molecules are merely rearranged into a different crystal structure, the density changes by only a few per cent. But in a transition to a metallic phase, in which the molecules themselves are partially destroyed, the increase in density will be of the order of 100 per cent.

The transition of a non-metal to a metallic phase is not a common occurrence in the laboratory. Usually a pressure of the order of a million atmospheres is necessary to make a non-metal metallic, and the highest pressure so far attained is only 100,000 atmospheres. But both metallic and non-metallic modifications of a few elements exist under laboratory conditions; examples are white and grey tin, metallic and yellow arsenic, black and yellow phosphorus. The metallic modification is always considerably denser; metallic arsenic is more than 2·5 times as dense as the yellow allotrope. The new interpretation of the core in terms of a phase transition is compatible with all seismic evidence of the earth's internal structure, and it accounts for some features not previously explained.

The new theory receives considerable support from the observed mean densities of the terrestrial planets. Jeffreys[2] has shown that, on the iron core hypothesis, the terrestrial planets have different chemical compositions; the smaller planets have relatively smaller cores, and so smaller proportions of iron. This is difficult, if not impossible, to reconcile with the planets having a common origin. The difficulty is removed by the new interpretation of the core. The new theory, together with the assumptions current in geophysics, implies that the variation in density within the earth is due mainly to the influence of pressure and not to changes in chemical composition. It is true that the crust contains a number of chemically distinct layers, but they account for only one per cent of the total mass. The pressure – density relationship for the material of the earth, which can be derived from seismic data[3], has been used to compute the mean densities of smaller planets of similar composition. It is found that all the terrestrial planets have the same chemical composition[1]. The smaller planets have smaller cores because of their smaller central pressures; and in the smallest planets, Mars and Mercury, the pressures are too low to support a core.

In the course of these calculations on the terrestrial planets, it was found that the smallest planetary cores are unstable and so would not occur in Nature. This feature is a direct consequence of the main assumption underlying the calculations, namely, that the jump in density at the boundary of the core is controlled by pressure. This phenomenon, which has recently been examined in some detail by Lighthill[4] and myself[5], may have played a significant part in the evolution of the solar system. To illustrate the effect, I have made calculations[5] on planets composed of a material which has a constant density ρ_0 at all pressures below a critical pressure p_c, and a constant density $\lambda\rho_0$, which is greater than ρ_0, at all higher pressures; in other words, both phases of the material are assumed to be incompressible. The central pressure always specifies the planetary configuration unambiguously; that is, the central pressure determines uniquely the mass and radius of the planet and the radius of its core. The radius of the core is necessarily an increasing function of the central pressure. But, for very small cores, the mass and radius of the planet are decreasing functions of the central pressure if the density jump at the boundary of the core exceeds 50 per cent (that is, if $\lambda > \frac{3}{2}$). The relationship between the mass M of the planet and the central pressure is illustrated in Fig. 1; the behaviour of the total radius is qualitatively similar. The mass M is a continually increasing function of the central pressure if the parameter λ does not exceed $\frac{3}{2}$; any planet of given mass has therefore only one possible equilibrium configuration. But if λ exceeds $\frac{3}{2}$, a mass M in a certain critical range

$$M_1 < M < M_0 \qquad (1)$$

is compatible with three different planetary configurations, denoted by A, B and C in the diagram. Configuration A has no core, and B has a smaller core than C. In general, the three configurations have different total radii and different degrees of stability.

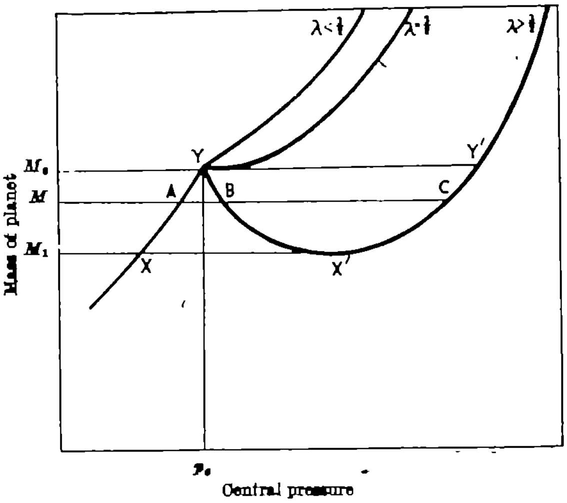

Fig. 1. Behaviour of the mass M of a planet as a function of the central pressure

Lighthill[4] has extended these considerations to the general case of planets composed of a material the density of which is a continuous function of the pressure up to a critical pressure p_c, and at the critical pressure the density is assumed to jump discontinuously from ρ_0 to $\lambda\rho_0$. Lighthill has shown that the derivative (dM/dP) of the mass of the planet with respect to the central pressure P changes discontinuously by a factor

$$(3 - 2\lambda)/\lambda^2 \qquad (2)$$

when the central pressure is equal to the critical pressure p_c. The derivative with respect to P of any other bulk characteristic, such as the radius of the planet, changes by the same factor. This factor is positive if λ does not exceed $\frac{3}{2}$, and so the mass M is a continually increasing function of the central pressure as shown in Fig. 1. But the factor (2) is negative if λ exceeds $\frac{3}{2}$, so that (dM/dP) changes sign. As the mass M cannot decrease with P indefinitely, the behaviour must be qualitatively as shown in Fig. 1. The earlier considerations therefore apply also in the general case of a compressible material. Using Bullen's[3] estimate of the density distribution within the earth, it is found by numerical integration that the planet with its centre at the critical pressure has the following mass and radius:

$$M_0 = 0{\cdot}80\, M_E, \qquad R_0 = 6{,}300 \text{ km.}, \qquad (3)$$

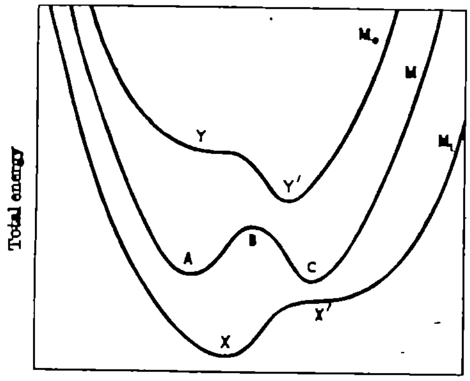

Fig. 2. Energy of a planet as a function of its total radius

M_E being the mass of the earth. The mass range $(M_0 - M_1)$, in which a planet has three possible equilibrium configurations, is only about 0·02 M_E. The total radii of different configurations of the same planet may differ by more than 100 km.

Fig. 2 shows schematically the energy of a planet as a function of its total radius; the letters A, B, etc., refer to the same equilibrium configurations as in Fig. 1. The middle curve refers to a general mass in the interval (1). Configurations A and C with minimum energies are stable; A has no core, and C has a large core. All configurations with small cores are of type B and are unstable; a small disturbance will cause a transition to either A or C. It is estimated that for stability the core of a terrestrial planet must be at least 1,000 km. in radius. For this reason the phenomenon is referred to as "the instability of small planetary cores". The top and bottom curves in Fig. 2 refer to the masses M_0 and M_1, which are special cases. For these masses a maximum and a minimum in the energy diagram coalesce to give a point of inflexion, and there is only one stable configuration for each mass. For mass M_0 the stable configuration is Y', which has a core; for mass M_1 the stable configuration is X, which has no core. The total energy of the stable configuration C with a core may be greater than or less than that of configuration A without a core, depending on the mass of the planet. The difference in energy between the two stable configurations is greatest near the ends of the critical mass range (1), that is, for masses near M_0 and M_1. The energy difference is estimated to be 10^{36}–10^{37} ergs—sufficient to remove from the surface of the planet a mass between 0·001 M_E and 0·01 M_E. Earthquakes release about 10^{25} ergs per year, and an atomic bomb about 10^{21} ergs. Thus if a planet were to undergo a transition from one configuration to another, the energy released would be enormous by ordinary standards. The transition would take minutes, or at most hours, and the energy released in this brief period would exceed that released by earthquakes during the whole of geological time. The energy liberated is always partly in the form of vibrations of the planet as a whole, but in some transitions a large fraction of the energy goes into blast waves. These blast waves, the pressure amplitude of which will be hundreds of thousands of atmospheres, will travel through the planet to the outer surface. The material on the surface will be shattered by the sudden impact of such large pressures, and fragments may fly off the planet into space. The mass of material removed may be of the order of 0·001 M_E. It is tentatively suggested that this mechanism may have been responsible for meteorites, and possibly also for the asteroids.

A planetary transition of the type envisaged will occur if the planet's mass M crosses the critical range (M_0, M_1) in either direction. The planet's mass could have changed gradually due to the aggregation of material or to the loss of light elements, depending on the mode of formation of the solar system. Alternatively, a planet could cross the critical range because of changes in the critical masses M_0 and M_1, which are functions of the internal temperature of the planet; a reasonable change in temperature could alter the critical masses by 10 per cent, and the mass of Venus is only 2 per cent greater than M_0. A planet must acquire a core if it crosses the critical mass range (1) in one direction, and it must lose its core if it crosses in the opposite direction. The core must be large at formation or disappearance since small cores are unstable; the planet must therefore undergo a transition of the type described. Venus and the earth may have undergone such transitions. The idea of an 'exploded planet' is an old one, but this mechanism makes an 'explosion' plausible for the first time. The irregular shapes and rough surfaces of the asteroids suggest that they have originated in this way. Meteorites also seem to be fragments of an 'exploded planet'. Local chemical separations, such as are apparent in stony meteorites and are necessary to account for iron meteorites, could only have occurred in a planet. In my opinion, the material of the earth below the crustal layers probably consists of ultrabasic rock with pockets of iron, such as would correspond to a representative mixture of all meteorites. Brown and Patterson[6] have recently advanced strong chemical evidence that meteorites were formed at high pressures, such as would occur in the central regions of a small planet or in the outer layers of Venus or the earth.

The present theory differs in one important respect from the old concept of an 'exploded planet'; the material removed is representative of the surface layers and not necessarily of the whole planet. Meteorites are not, of course, of the same chemical composition as surface rocks; but the transition envisaged would occur before the interior became quiescent, and so before the formation of a crust. As regards radioactivity, meteorites may be abnormal if they have originated from the surface layers of a planet; the earth's radioactivity is largely concentrated in the outer 50 km. There is circumstantial evidence that the radioactive content of meteorites is an order of magnitude greater than that of the earth as a whole.

Bullen[7] has suggested that the phenomenon under discussion may have a bearing on the origin of the moon. He reconsiders the old theory in which the moon is supposed to have been torn from the earth by a resonance tidal action of the sun. This theory has been in disrepute since Jeffreys[8] pointed out that internal damping would prevent the necessary build-up of amplitude. Bullen proposes that the function of the tidal resonance is primarily to induce a planetary transition of the type C to A in Figs. 1 and 2. He assumes that the primitive earth-moon body, due to its higher central pressure, contained within the central core another and denser core. This additional core disappeared when the moon was formed, and its disappearance released the energy necessary to separate the moon from the earth. It is highly desirable that this idea be examined quantitatively.

OBITUARIES

Academician S. I. Vavilov

THE death of S. I. Vavilov at the age of sixty, which occurred on January 25 of this year, was a heavy loss to science in the Soviet Union, for he was not only a great man of science but, even more, one of the founders of science in his country.

Vavilov entered the University of Moscow in 1909 and worked under F. N. Lebedev, whose researches on the physics of light absorption were to furnish the theme of Vavilov's scientific career. His first paper, on "The Effect of Heat on the Fading of Dyestuffs", was written before he left the University in 1914 with other members of the staff and students as a protest against police persecution in the University. After a period of war service, in which he worked on radio physics, Vavilov found himself one of the small band of trained physicists, not more than forty in number, with the immense task of building up physical teaching, research and application in the new Soviet Republic. He managed to combine this with the furtherance of his own research in the field of physical optics. The chief contribution was embodied in some hundred papers on fluorescence and phosphorescence of dyestuff molecules. He elucidated, by a combination of experimental and theoretical study, the laws governing the quantum yield of fluorescence, the maintenance of excited states, particularly at low temperatures, and the explanation of impurity quenching, and self-quenching of fluorescence. This work, which linked with that of Frank and Pringsheim, he summed up in a paper in 1945[1] and in a semi-popular book, "The Microstructure of Light"[2]. His study of fluorescence led him into the field of the physiology of vision, especially in the quantum effects that can actually be observed at very low light intensities. He was also, in his latter years, largely responsible for the study of the 'shock wave' radiation from electrons moving faster than the speed of light in the medium through which they pass.

Vavilov's scientific work was always closely linked with that of the organization of research. Before 1917, Russia had imported practically all optical apparatus from abroad, largely from Germany. It was then decided to build up a State Optical Institute in Leningrad, where research and development were to lead into full-scale production. Vavilov played a major part in the building up of the Institute and, in particular, in establishing the production of fluorescent lighting.

These activities by no means used up all his intellectual capacity. Indeed, it was from them that he acquired an intimate knowledge and practical experience of the relation of science to social needs. He showed this first in his studies on the history of science; British readers will remember his contribution to the Newton tercentenary, where he threw new light on Newton's atomism and its intimate connexion with optics and chemistry[3]. He had also thought profoundly on the philosophy of physical science[4], particularly of the factors that led to the twentieth-century revolution in physics, which he attributed in the first place to Maxwell's use of mathematical hypotheses. On the practical side, his wide understanding qualified him first to contribute to and ultimately, as president of the Academy, in 1945 to co-ordinate and direct the work of Soviet scientists in the solution of the great practical problems involved in transforming the economy of the country. He was a deputy both to the Russian and Union Supreme Soviets, and his advice was taken in all problems involving science[5,6]. In the international field, despite all difficulties, he was always a firm supporter of the need for the co-operation of scientific workers of all countries in building a peaceful world.

Vavilov as a man had a quiet dignity. He did not impose himself on others but commanded respect by the rationality of his judgments and the integrity of his character. His death in harness was probably due to overwork; but he had already contributed more than his share to his country. He will be counted with Lomonosov as one of the great builders of science in the U.S.S.R.

Dr. K. C. Bailey

DR. KENNETH CLAUDE BAILEY was born in 1896 and educated at St. Andrew's College, Dublin. He entered the University of Dublin in 1913, where he immediately earned fame by taking, when still only a junior freshman, first place in the examination for classical scholarships, an honour which is usually obtained only by men of senior freshman or junior sophister standing. The First World War, in which he served from 1915 until 1919, interrupted his academic career, and when he returned to Trinity College after demobilization he continued his classical course and also commenced to study experimental science. In 1921 he obtained brilliant degrees in both these subjects, and afterwards worked for about a year in the University of Toulouse under Prof. Sabatier, where he obtained a doctorate in science. A few years after his return to Trinity College as lecturer in chemistry he was elected in 1926 to a fellowship, which he continued to hold until his death.

He married in 1923 Miss Dorothy Lavelle, who is also a science graduate of the University of Dublin, where their only child, Miss Pauline Bailey, is now studying medicine.

In the space available it is quite impossible to give any adequate picture of Dr. Bailey's multitudinous activities since 1926. It may be said that his principal public interests were mainly threefold, embracing chemistry, classics, and the administration of the affairs of Trinity College, Dublin. In all three he did notable and memorable work.

His reputation as a chemist will probably rest on his work on the inhibition of chemical reactions, on which he contributed a long series of papers to the scientific publications of the Chemical Society, the Royal Irish Academy, the Royal Dublin Society, and others. In 1937 he published his book, "The Retardation of Chemical Reactions", which appears to be the first general treatment of this subject that had appeared in any language. It represents the experimental and literary research of more than a decade. Its thoroughness can be judged from the fact that the bibliography alone contains some 1,600 references to original papers. He intended to publish a second edition, and had done most of the preliminary spade-work, but unfortunately his other occupations postponed the fulfilment of this intention, and owing to this occurrence chemical science is undoubtedly the poorer. During the Second World War he assisted the Irish Emergency Research Bureau in its attempt to alleviate the local shortage of certain essential materials. Among other problems, he worked out the details of the production of potassium chlorate, needed for the match industry, from sodium chloride and kelp. This process was eventually developed on a fairly large scale towards the end of the War.

On the classical side, Bailey published two books, the titles being "The Elder Pliny's Chapters on Chemical Subjects", and "Etymological Dictionary of Chemistry and Mineralogy", in the latter of which his wife, Dr. Dorothy Bailey, collaborated. He was also greatly interested in the development and history of chemistry, and wrote several articles on these subjects for various journals.

It might be thought that with his teaching duties as lecturer, and later as professor of physical chemistry, and the quantity of original work he produced, Bailey would have found little time for administrative duties. This, however, is far from true. He held the onerous and rather thankless post of Junior Dean of Trinity College for a period of eleven years, a term of office which has only once been exceeded in length during the history of the College. He was a member of the Board of the College for twenty years, first as a representative of the Junior Fellows, and since 1942 as registrar. During this period he was instrumental in introducing several excellent reforms. It is perhaps a pity, from the scientific point of view, that his duties as registrar very largely curtailed his original chemical research work after 1942, although he continued to lecture in the Chemical School until his retirement, due to ill-health, in October 1950. He did, however, find time to write an interesting and very readable volume entitled "The History of Trinity College Dublin from 1892 to 1945" during his later years.

Of Bailey's personal characteristics one finds it hard to write. He was always the most pleasant and courteous of colleagues, always ready to help in any problem proposed to him. As might be expected from a man of his calibre, he held very definite views on many subjects; but he was never dictatorial in expressing them, and always willing to listen to contrary opinions.

Trinity College, Dublin, may long and truly mourn

> "A man so various, that he seem'd to be
> Not one but all mankind's epitome".

J. H. J. Poole

NEWS and VIEWS

Zoology at University College, London : Prof. D. M. S. Watson, F.R.S.

The new term has begun at University College, London, without the official attendance of this distinguished zoologist. It was in 1912 that Mr. David Watson joined the College staff after a brilliant student career at the University of Manchester. Already he was the author of papers to which reference is still made. From that date until 1921 he was lecturer in vertebrate palæontology. He was absent, it is true, during part of the First World War as a lieutenant in the R.N.V.R.; but even there his palæontology was not forgotten, and he was largely responsible for the design of a pterodactyl type of aircraft that later was to take the air. In 1921 he succeeded Prof. J. P. Hill in the Jodrell chair of zoology and comparative anatomy at University College. There he has created not only a school of zoology, but also has attracted numbers of graduate students in zoology and palæontology who have themselves gone to chairs of zoology or geology. Some years before the Second World War he had the task of remodelling commercial premises to his departmental purposes in the Malet Place buildings of the College.

During these arduous and fruitful years Prof. Watson has also made opportunities for world-wide travel and for collecting expeditions in which he has visited Canada, the United States, South Africa, the Soviet Union, Scandinavia and Ceylon, and he has visited every site of importance to vertebrate palæontology in Great Britain. His many contributions to the study of fossil fishes, on the origin and development of the amphibians, and on many groups of fossil reptiles are too well known to need comment here. These, with his ease and clarity as a lecturer, have made him welcome in many assemblies and conferences. Among his many honours is the Darwin Medal of the Royal Society. Since the War he has been a trustee of the British Museum. Prof. Watson was sixty-five on June 18 and the event was celebrated in his department with a tea-party, when he was presented with an album of photographs and signatures of many of his friends, pupils and admirers from all over the world. His last term of office was clouded by an illness. Happily he has recovered his full vigour and will continue his researches in the familiar surroundings of University College. His friends and colleagues will wish him many happy years of work, and pleasure in his library and his collection of Oriental art. Prof. Watson has been succeeded by Prof. P. B. S. Medawar, Mason professor of zoology in the University of Birmingham (see *Nature*, 160, 14; 1947).

Television in the North of England

The scheme of the British Broadcasting Corporation for establishing television on a nation-wide basis moved another step forward on October 12, when the North of England station at Holme Moss was opened for public service by Lord Simon of Wythenshawe, chairman of the governors of the

Corporation. In order to cover the greatest possible area in the central and southern portions of the North of England, the site of the Holme Moss station was chosen in a very high and isolated region some sixteen miles east-north-east of Manchester. The altitude of the site is 1,700 ft.; and this, with the mast, which is similar to that of the station at Sutton Coldfield, Birmingham, results in the height of the aerial being some 2,450 ft. above sea-level. The carrier frequencies of the vision and sound transmitters are 51·75 and 48·25 Mc./s., and the corresponding powers are 45 and 12 kW., respectively. The resulting range for good and reliable reception is expected to be between fifty and seventy miles, depending upon local conditions and the nature of the intervening terrain. It has already been reported that the opening programme was received clearly in North Wales at a distance of about eighty miles.

Due to the exposed position, special precautions have been taken in the design of the buildings and the mast to ensure that they will stand up to the severe blizzards and gales which will almost certainly be experienced during most winters. The task of maintaining and operating the station will not be easy or pleasant; and arrangements have been made for the staff to live on the station when access becomes difficult or impossible owing to snow and ice. The Holme Moss transmitter is connected to the Birmingham and London television stations by a special coaxial cable installed by the General Post Office. This cable transmits programmes in either direction as required; and it provided a very satisfactory means of viewing, in the London area, the inaugural ceremony of the new station in the Manchester Town Hall, and a programme from the Theatre Royal, Leeds, on the following evening.

Thousandth Issue of *The Practitioner*

First published in 1868, *The Practitioner* has celebrated its thousandth issue (vol. 167, October 1951), providing, in addition to its usual features, thirteen valuable articles on advances in various aspects of medicine and surgery. All these articles are written by distinguished specialists in the fields they cover. There is also an article by Sir Henry Dale entitled "The Changing Face of Medicine, 1868–1951", another by Sir Henry Bashford on "The Social Background of Medicine" and a third by Dr. W. N. Pickles entitled "Trends of General Practice: a Hundred Years in a Yorkshire Dale". The whole issue thus constitutes an epitome of the immense advances that have been made in the past hundred years or so, and it worthily enshrines the very great benefits that medicine has conferred upon us during this period. In these benefits the animals, especially the domesticated animals, have shared, and one of the inspiring trends, not specifically noticed in these pages, is the increasing co-operation between the medical and veterinary professions. It is impossible to select from so many excellent articles any that are more valuable than the others. The layman will find a great deal that will interest and encourage him in the three papers already mentioned; Dr. Pickles, in his sketch of three generations of practitioners, re-creates for us that great and tireless 'guide, philosopher and friend', the general practitioner of an age that many readers will know only in literature. *The Practitioner* has proved, with this issue, that it is as vigorous and progressive as it has ever been, and it would not be easy to find, for any scientific journal, contributors more skilled in the art of explaining, pleasantly and effectively, the intricate matters that are the busy medical practitioner's everyday concern.

Institute of Metal Finishing

The Council of the Electrodepositors' Technical Society announces that application for official incorporation has now been granted; also permission has been given for the adoption of a new title embracing metal finishing generally (excluding only vitreous enamelling). This is in accordance with the general policy of the Society to extend its field beyond electrodeposition processes to include metal finishing generally, with which the bulk of its members are vitally concerned. The new title by which the Society will henceforth be known is 'The Institute of Metal Finishing incorporating Electrodepositors' Technical Society Limited'. The original aims and objects of the Society, namely, to promote the study of, and disseminate information on, electrodeposition and cognate processes as widely as possible, are in no way affected by these changes. The sphere of interest has now been significantly widened and the Council is of the opinion that this will bring with it corresponding benefit to the membership. The executive officers and Council of the Electrodepositors' Technical Society have become the officers of the new Institute. The present executive officers are: *President*, Mr. H. Silman; *Honorary Secretary*, Dr. S. Wernick; and *Honorary Treasurer*, Mr. F. L. James. The headquarters of the Institute are at the Northampton Polytechnic, St. John Street, London, E.C.1; all communications should be addressed to the Honorary Secretary at 27 Islington High Street, London, N.1.

Agricultural Research Council: Potato Genetics Station

The Commonwealth Potato Collection, Huntingdon Road, Cambridge, which was formerly a responsibility of the Commonwealth Agricultural Bureaux, has recently been transferred by agreement to the control of the Agricultural Research Council and will in future be known as the Potato Genetics Station. In 1939 the Commonwealth Agricultural Bureaux organized an expedition to Mexico and South America to collect varieties of wild and cultivated potatoes in their native home; and the collection based on the samples brought back has been housed since 1945 in a building erected, through the generous financial assistance of the Nuffield Foundation, on a site provided free of cost by the University of Cambridge. In the past ten years, description and classification of the collection have been completed, and the reactions of the material to certain virus diseases, eelworm, late blight, wart, frost and other factors have been studied. Some work on the chemical content of tubers has been carried out, but much remains to be done. This comprehensive collection would seem to offer valuable material for comparative biochemical studies in a vegetatively propagated crop plant. Students in several Commonwealth countries co-operated in this first phase of the work, and material has been widely distributed for the use of potato breeders at home and overseas.

The change in administrative responsibility marks the beginning of a second phase of development, in which the collection will be used mainly for genetic research. The programme includes studies of resistance to various diseases, with a view to the synthesis of lines for the potato breeder, and investigation of the general problems of genetical history and differentiation in the tuberous species of *Solanum*. The valuable research material that has been assembled will thus continue to be used to the ultimate advantage of the potato industry. The Potato Genetics Station is under the direction of Dr. K. S. Dodds.

Acustica: A New International Journal

The first two numbers have recently appeared of *Acustica* (Zurich: Hirzel-Verlag, 1951; 36 Swiss francs a year), a new international journal sponsored by the Acoustics Group of the Physical Society of London. There have been previous attempts to start national acoustical journals in both France and Germany, but neither of these survived the Second World War. In recent years hopes have been expressed for a revival of these and for the setting-up of a journal in English on the eastern side of the Atlantic, sponsored by the respective groups of scientific workers and technicians interested in acoustics. Eventually it was decided to combine these efforts and to found a journal which should publish articles received in English, French or German of any origin but particularly those coming from European countries and from countries associated therewith, such as the British Commonwealth. Dr. C. W. Kosten, of Delft, was appointed editor-in-chief, and Dr. E. G. Richardson, of King's College, Newcastle upon Tyne, is the editor for papers submitted in the English language. *Acustica* will appear six times a year and will publish from time to time additional one-language supplements under subvention by one or other of the national groups. (One such supplement, in German, has already appeared.) For the main journal, up to the present more papers have been received in English than in any other language, but those printed in the first two issues include some in all three languages. Between them they cover the subjects of building acoustics, subjective sound, musical acoustics, ultrasonics, loud-speakers and the history of sound. It is indeed the aim of the editors that fundamental, and not only technological, aspects of sound shall be well represented in the journal.

Study of the Arthropod Mandible

It is generally accepted that the mandibles of an arthropod have evolved from a pair of limbs in a primitive ancestral form, though precisely which part or parts of the limb is involved is still a subject of discussion. The typical, primitive arthropod limb consisted of a basal coxopodite or coxa and a distal segmented telopodite. The coxa was articulated dorsally on the tergum and ventrally on the sternum, and the limb was moved antero-posteriorly probably by a pair of dorsal muscles originating from the tergum and a pair of ventral muscles originating from the sternum or an endophragmal projection therefrom. These muscles may be termed the dorsal promotor and remotor and the ventral promotor and remotor, respectively. A change in the position of the points of articulation or in the places of origin of the muscles or both would, of course, bring about a change in the direction of movement of the limb. Starting with these quite reasonable assumptions, R. E. Snodgrass has carried out a most interesting series of "Comparative Studies on the Jaws of Mandibulate Arthropods" (Smithsonian Misc. Coll., 116, No. 1; pp. 85. Washington, D.C.: Smithsonian Institution, 1950). He points out that in many Entomostraca, some Malacostraca and the Machilidae, the mandible most clearly resembles this idealized coxa in structure and musculature, bearing in mind that there is no sternum as its place is occupied by the mouth. The work traces the various modifications and specializations that are to be found in all groups of mandibulate arthropods. The text is illustrated with twenty-five text-figures and the majority of these have seven or eight individual diagrams.

Annual Conference of Aslib

In what circumstances are mechanized aids quicker or slower than human beings in selecting information from a wealth of coded material? Can the flow of work in a library be usefully compared with that in a process plant when planning layout? Would the use of intelligence and aptitude tests help in choosing a better information officer? These are typical of the questions raised at the twenty-sixth annual conference of Aslib held during October 5–8 at Ashorne Hill, the conference centre of the Iron and Steel Corporation near Leamington Spa, and attended by nearly two hundred and fifty delegates. The theme of the conference was 'design for efficiency'. The particular fields in which problems of increasing efficiency were studied were: international bibliography; optimum use of staff and training the user; and the future development of Aslib. The formation of subject groups within the framework of Aslib in the fields of aeronautics, food and agriculture, textiles and economics stimulated lively discussion. Some constructive co-operative plans for rationalization in the purchase, listing and loan of periodicals, for exchange of staff, and for translation have already been initiated. In the sessions on choosing, training and directing staff, and on training and directing the (unchosen) user, scientific and statistical methods of assessing the problems attracted the interest of delegates. It was noticeable that attempts to measure the capabilities of persons and the efficiency of processes are increasing. Unesco's efforts to stimulate the development of bibliographical services in under-developed areas and to tidy up the existing services elsewhere were described in a paper submitted by the head of the Libraries Division of Unesco. Added interest was provided in this session by contributions both from members of the Organization for European Economic Co-operation (O.E.E.C.) mission at present touring Europe to study technical information services, and also from delegates recently returned from the Conference of the Fédération Internationale de Documentation in Rome. The Conference not only provided the usual stimulus of contacts between specialists, but also raised problems that may be profitably pursued by smaller groups in the future.

University of Birmingham

The following appointments have recently been made in the University of Birmingham: P. J. Palmer, formerly of the Boulton Paul Aircraft Co., to be lecturer in civil engineering; J. H. O. Varley, to be lecturer in metallurgy. The following resignations from the University have been announced: Dr. E. S. Twyman, lecturer in botany, on appointment as professor of botany in Rhodes University, Grahamstown; W. S. Norman, lecturer in chemical engineering, on appointment as lecturer in chemical engineering in University College, London; Dr. A. J. Wilson, lecturer in mechanical engineering, on appointment to the Metals Division of Imperial Chemical Industries, Ltd.; Dr. Mary Gregg, lecturer in botany, on appointment as lecturer in botany in University

College, Dublin; Dr. Vera Norris, senior statistical officer in the Department of Medical Statistics, on appointment as medical statistician at the Maudsley Hospital, University of London.

Postgraduate Agricultural Scholarship Awards

THE Ministry of Agriculture and Fisheries has awarded postgraduate research and training scholarships in the following subjects, tenable in the first instance at the university or institute shown for periods up to three years from September 1, or later. *Agricultural Economics:* E. A. Attwood, School of Agriculture, Cambridge; and K. C. Abercrombie, P. N. Barker, S. A. Bradburn, A. A. Marsh, J. D. Sykes and Miss F. R. Walker, Agricultural Economics Research Institute, Oxford. *Agricultural Engineering:* P. R. Attwood, D. P. Blight, D. J. B. Calverley, A. J. Crowther, J. L. Manson, W. T. B. Marchant, J. J. Thomas and M. A. Keech, King's College, Newcastle upon Tyne. *Husbandry:* A. J. Abbott, W. H. Broster, S. C. Meadowcroft, P. Radford, K. W. G. Shillam and Miss J. P. Tibbitts, University of Reading; D. Archer and R. J. Colley, University of Leeds; B. F. Bland, A. W. Court, F. K. Deeble, B. C. Knight and R. P. Voelcker, School of Agriculture, Cambridge; Miss D. E. Fisher, University of Nottingham; J. Sherwell and B. R. Watkin, Wye College, University of London; and J. G. Watkin Jones, Rowett Research Institute, Aberdeen. *Agricultural Statistics:* Miss A. W. Boyes, University of Oxford; and F. R. Latham, University of Manchester.

Commonwealth Fund Fellowships for Study in the United States

THE Commonwealth Fund of New York (41 East 57th Street, New York 22) is again offering a number of Commonwealth Fund fellowships to British subjects for study and travel in the United States. The fellowships provide for all expenses of travel, study and living, with some adjustment for married men with families. The fellowships, which are open to British men or women who are not normally resident in or near the Americas and who have not previously worked or studied for more than a few months in the United States, are offered annually in six categories as follows. *Ordinary:* twenty fellowships to graduates of a university in the United Kingdom of Great Britain and Northern Ireland. Candidates must be available in London for interview in March 1952; age, 23–35; tenure, 12–21 months; applications by December 15. *Home Civil Service:* five fellowships to permanent members in the higher ranks of the Civil Service in Great Britain, three for the administrative grades and two for the scientific and professional grades. Age, less than 40; tenure, 6–12 months; applications by December 31 to the Treasury. *Dominion Civil Service:* five fellowships to Civil servants in the Governments of Australia, New Zealand and South Africa. Age, less than 40; tenure, 12–21 months; applications by February 1. *Colonial Civil Service:* two fellowships to Civil servants in the Governments of the British Colonies, Protectorates, and Trust Territories. Age, less than 40; tenure, 12–21 months; applications by December 31 to the Colonial Office, London. *Journalism:* three fellowships to journalists practising in the United Kingdom and engaged on the opinion-making or broadly editorial side of their profession. Age, 23–35; tenure, 9–15 months; applications by January 1, 1952. *American Studies:* four fellowships will be available to faculty members appointed to or holding posts in American studies in universities in the United Kingdom, candidates to be nominated by their universities; tenure, 4–12 months; these fellowships are not limited by previous study in the United States. Application forms and further details of these fellowships can be obtained through British universities or through government departments, or from the Warden, Harkness House, 35 Portman Square, London, W.1.

Announcements

H.R.H. the Duke of Edinburgh has been elected an honorary member of the British Institution of Radio Engineers.

THE Franklin Medal, the highest honour given by the Franklin Institute, Philadelphia, has been awarded to Sir James Chadwick, master of Gonville and Caius College, Cambridge, for his work in nuclear physics.

PROF. P. TH. OOSTERHOFF, Sterrewacht, Leyden, has been appointed assistant general secretary of the International Astronomical Union. Prof. Bengt Strömgren remains general secretary of the Union.

THE Committee of the Privy Council for Agricultural Research and Nature Conservation has reappointed Sir Alan Drury, Director of the Lister Institute, to the Agricultural Research Council for a further term, and has also appointed Prof. S. J. Watson, professor of agriculture and rural economy in the University of Edinburgh, to fill the vacancy caused by the retirement from the Council, on completion of his term of office, of Prof. T. J. Mackie.

THE following appointments have been announced from the University of London: Dr. Ruth Bowden, to the University chair of anatomy tenable at the Royal Free Hospital School of Medicine; Dr. R. J. Harrison, to be head of the Department of Anatomy at the London Hospital Medical College, with the title of reader in anatomy in the University in respect of this post.

THE Société Française de Métallurgie will be holding a series of autumn sessions during October 22–27 at the Centre Marcelin Berthelot, Maison de la Chimie, 28^{bis} rue St. Dominique, Paris 7^{e}. On each day papers will be read on a number of metallurgical topics. Further details can be obtained from the Society at 5 Cité Pigalle, Paris 9^{e}.

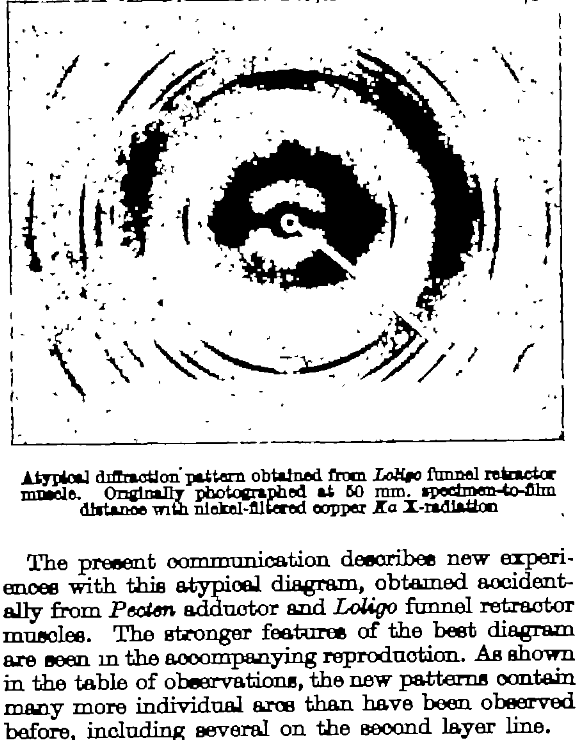
THE British Standards Institution has recently published "Methods for the Analysis of Soaps" (B.S. 1715: 1951. Pp. 42; London: British Standards Institution, 1951; 5*s*. net). This document gives both the British Standard methods and also the methods of the International Commission for the study of fats. Full details of the analytical methods and of any special apparatus required are outlined.

THREE textile research fellowships have been created by the Commonwealth Scientific and Industrial Research Organization to enable research men trained in physics, chemistry or engineering to obtain special experience in textile science in the United Kingdom. The fellowships are being financed from money made available by the Associated Woollen and Worsted Textile Manufacturers of Australia. Fellows will be appointed for twelve months. They will receive a salary of £A1,000 per annum, plus travelling expenses. Further details can be obtained from the Secretary, C.S.I.R.O., 314 Albert Street, East Melbourne.

THE 'LOTMAR-PICKEN' X-RAY DIFFRACTION DIAGRAM OF MUSCLE

By Prof. RICHARD S. BEAR and Dr. CECILY M. M. CANNAN
Department of Biology, Massachusetts Institute of Technology, Cambridge, Mass.

MUSCLE specimens normally yield the α-type of X-ray diffraction at wide angles[1]; but on rare occasions another pattern is obtained exhibiting characteristics of an oriented, highly crystalline substance[2,3]. Assuming this to be a protein derived from a fibrous component of muscle, Lotmar and Picken[3] developed a detailed structure which has been widely discussed. Because of lack of reproducibility, confirmation of their conclusions has not been readily possible, and the suggestion that the Lotmar-Picken substance is protein has already been questioned[4]. Nevertheless, Pauling and Corey[5] have also recently used the Lotmar-Picken data to consider the structure of fibrous proteins.



Atypical diffraction pattern obtained from *Loligo* funnel retractor muscle. Originally photographed at 50 mm. specimen-to-film distance with nickel-filtered copper *Kα* X-radiation

The present communication describes new experiences with this atypical diagram, obtained accidentally from *Pecten* adductor and *Loligo* funnel retractor muscles. The stronger features of the best diagram are seen in the accompanying reproduction. As shown in the table of observations, the new patterns contain many more individual arcs than have been observed before, including several on the second layer line.

The Lotmar-Picken diagram has now been observed in examples of the major types of muscle: smooth and striated, vertebrate and invertebrate. So far as we are aware, the pattern has never been derived from tissues other than muscle. In every case the orientation effects are closely related to those of the fibrous elements of the muscle.

The conditions required for development of the Lotmar-Picken crystals are still not evident. The present examples were air-dried under tension sufficient to maintain approximately resting length and had been stored for a few days (*Pecten*) to two months (*Loligo*, at 4° C.) before X-ray examination. A companion *Loligo* specimen, taken from the other side of the same squid funnel and treated similarly, except for stretching 30 per cent, exhibited the usual α-diagram. Attempts to test the function of tissue autolysis in the Lotmar-Picken effect, suspected in the *Pecten* case, failed to show any connexion.

Possibly the Lotmar-Picken crystals are developed at the expense of the fibrous structures of the muscles. Under comparable conditions of examination, samples yielding the Lotmar-Picken pattern show the α-diagram and associated small-angle diffractions (type II of Bear[6], similar to those of actin films[1]) somewhat less intensely than is normal.

There is little doubt that the present patterns have the same origin as those of previous investigators. Although several minor differences in the line positions and intensities may be noted in the table of observations, serious difficulties arise only with respect to the following positions: (*a*) on the equator near $\frac{\sin\theta}{\lambda} = 0·052$, and (*b*) near the meridian at the first layer line. Both these areas are ones to which the normal α-type diffraction, plus a certain amount of diffuse scatter, contribute a confusing background. As the reproduction shows, however, the present pattern offers particularly good opportunity for distinguishing the Lotmar-Picken reflexions from others.

DIFFRACTION POSITIONS ON ATYPICAL MUSCLE DIAGRAMS

Figures are $\frac{\sin\theta}{\lambda}$ values. Letters indicate intensities as follows: S = strong, M = moderate, W = weak, VW = very weak.

Figures enclosed in parentheses are for background reflexions of the normal muscle α-diagram. True diatropic reflexions, corresponding to b_0 = 5·29 A., are indicated by †. The equatorial region at 0·200 and beyond was not covered by present films.

While showing good radial sharpness, all spots are arced sufficiently to make decision as to certain indices and unit-cell dimensions difficult. The fibre-axis translation (b_0) is the only cell element clearly distinguishable. All non-meridional arcs of the first layer line, as well as diatropic reflexions on the first and second layer lines, indicate a value for b_0 of 5·3 A., as compared with the 5·65 A. suggested by Lotmar and Picken.

One may also ascertain that interferences comparable in sharpness and intensity with the others are not present at the position of the diffuse equatorial spot corresponding to the 'side-chain' spacing of the α-diagram. Diffraction in this region played a prominent part in the considerations of Lotmar and Picken and of Pauling and Corey. Our results throw considerable doubt on the correctness of the previously suggested unit cell, and also deny the validity of any structural conclusions which require, on the atypical muscle diagram, strong equatorial diffraction corresponding to spacings of about 10 A.

Crystalline proteins should show large cells the dimensions of which are functions of the large lengths and/or breadths of the molecules. Although the abnormal *Loligo* specimen yielded a single, partially oriented (equatorial) diffraction, corresponding to a spacing of about 50 A., this is independent of the Lotmar–Picken diagram, since on occasion similar diffraction has been observed in muscles failing to show the distinctive Lotmar–Picken phenomenon. The oriented rings observed in such cases are like those yielded by phospholipids[7], which are common tissue contaminants.

There remains the possibility, if protein is involved, that the wide-angle diffractions represent intramolecular diffraction from individual protein particles. This is excluded by the radial sharpness and the spotted character of the observed diffractions, which could not be produced by particles of size less than that reported for intra-myofibrillar filaments (breadths c. 100 A.)[8]. Several of the interplanar spacings observed for the Lotmar–Picken substance are as small as 2 A. or less, a magnitude which, though not impossible for a protein, is smaller than is usually encountered.

Additional indication as to the nature of the Lotmar–Picken substance was found in experiments employing solvents to disperse this material. The abnormal *Loligo* specimen was divided and one portion subjected to distilled water, another to benzene, for two days. After drying, neither specimen yielded the Lotmar–Picken diffractions, exhibiting only the normal α-diagram. Dispersion by water is rather inconclusive; but the solubility in benzene may narrow the possibilities. The water had weakened the intensity of the 50-A. ring mentioned above; but benzene removed it entirely. The more bulky sample of *Pecten* muscle was extracted with benzene, and upon concentration of the extract by evaporation of solvent the residue yielded a small-angle ring (43 A.) but no evidence of Lotmar–Picken diffraction.

Probably the Lotmar–Picken substance, while related in origin to the fibrous elements of muscle, is not a protein. It is more likely to be a small organic molecular species which usually remains hidden by complex formation or solid solution within or near the fibrous components. On occasions, the circumstances of which are unknown, this material may be released to form separate crystalline phases, much as the lipid components of the nerve myelin sheath separate from the protein upon drying[9]. While this view denies that the Lotmar–Picken diagram is of any direct significance for the problem of protein structure, the diagram may still retain considerable interest for conceptions of muscle structure.

MOVEMENT OF PROTEINS ON FILTER PAPER

THE separation of proteins by chromatography has been described by several workers[1,2]. Recently, Franklin and Quastel[3,4] reported the separation of proteins on filter paper. They developed two-way chromatograms with a variety of solvents (sugars, amino-acids and sodium salts of weak dibasic or hydroxy acids). The importance of their work, and its possible value in clinical research, rendered it desirable to examine the movement of proteins on filter paper under the influence of different eluting solutions, and to follow the effect of the conditions employed on the appearance of the resulting chromatograms.

The factors concerned in the ultimate separation of a two-dimensional chromatogram are: (1) extension of the mixture from a single spot to form either an elongated band or a series of discrete spots along the origin of flow of the second dimension; and (2) separation of the components of this band to give the final pattern.

After certain preliminary experiments, it appeared doubtful whether either of these two conditions was fully met in the system under consideration, and further experiments were designed to study the

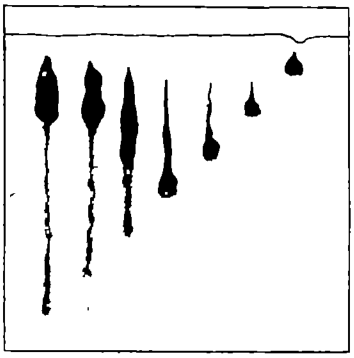

Fig. 1

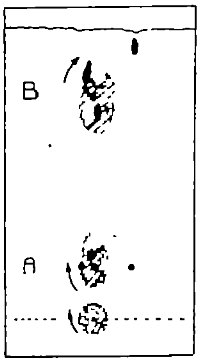

Fig. 2

Fig. 1. Diagram demonstrating the changing shape of protein spots at various intervals after the commencement of a chromatogram. The black area indicates the protein mass as demonstrated by ultra-violet fluorescence or iodine, the shaded area that which also stains blue with benzidine, showing that this indicator in part dissociates from the protein during the run

Fig. 2. Diagram demonstrating non-linear flow of solvent in neighbourhood of protein mass. When protein had reached *A*, spots of bromphenol blue were added at positions indicated. The relative movement of the component parts of the spot is shown by the positions of the bromphenol blue spots at *B*

mode of transport of mixtures of proteins such as occur in serum.

Following the conditions of Franklin and Quastel's experiment[4], serum and hæmin were mixed and 0·02 ml. dried on paper in a current of cold air. The chromatogram was developed by upward irrigation with 0·1 *M* glucose, lævulose, sodium glutamate, adipate malate or maleate solutions. To determine the shape of the protein mass after varying periods of time, spots were applied at increasing distances from the lower edge of the paper. When the solvent front had reached the uppermost spot and had flowed a distance of approximately 10 cm., the chromatogram was dried in a stream of cold air, and treated with benzidine (Fig. 1). There was a marked lag in the elution of the spot, leaving an indentation in the advancing front. Only after the solvent front had moved two or three centimetres ahead of the spot did elution commence. In further experiments small quantities of bromphenol blue were added to the chromatogram on either side of the mid-line of flow of the protein (Fig. 2). Material from the sides of the spots was eluted first and occasionally caused the production of "two separate fractions inside the finger" as observed by Franklin and Quastel[4]. Thereafter, owing to the inward flow of the solvent across the front of the spot, the tails fused and material from the rear was continuously carried to the front of the moving protein mass.

It was therefore apparent that the relative positions of the components of a mixture are dependent on certain factors not necessarily functions of its complexity. The protein is first segregated radially through the spot during drying, followed by peripheral elution. Secondly, infiltration and elution of the central portion which afterwards overtakes the material initially eluted causes the relative final positions of the fractions eluted from the centre and periphery of the original spot to depend on the distance the solvent front has travelled. It will be noticed that towards the end of a run of 20 cm., the protein is located as an oval spot only about twice the length of the original. Paper electrophoresis[5,6] of various portions of spots run under such conditions showed that at no stage in the process was there a linear distribution of the various components, albumin and globulin bands appearing in the final electrophoresis patterns of all areas of the spot. If by adequate manipulation of the conditions an elongated spot does result from the first run, this is again securely bound to the paper during drying, so that the developing solution is held back by the dried spot but eventually bursts through after its freely moving front has by-passed the spot by about 15 mm. The elongated protein trace is thus disrupted into a number of fractions. As many as eighteen have been observed immediately after the spot has been wetted out, if bromphenol blue is added to the protein initially. As the solvent front progresses, the faster-moving portions at either side flow inwards across the front of the protein, compressing the effective length of the complex of small spots, causing them to coalesce. Thus, the number of separate spots appearing on the final chromatogram depends on: (*a*) the length of the first run, since this affects the length of the spot; and (*b*) the length of the second run, since fewer spots are observed when this run is protracted.

It is also possible to show that the fractionation produced during the second run is not dependent on the existence of separate protein species in discrete positions on the paper. Spots of serum of varying length but containing the same volume were placed on the starting line, and developed with an appropriate solvent. The results showed great similarity to those obtained after a two-dimensional run.

Certain poly-hydroxy emulsifying agents were shown by Franklin and Quastel[4] to have the effect of increasing the number of fractions into which serum could apparently be divided. Since little or no separation may occur in the first direction, any increase in fractionation must be looked for in the second. This effect is apparently due to the greater degree of wetting-out occurring in those systems containing both protein and surface-active agent. Experiments with 'Span 20', sodium alginate and 'Tween 85' showed that the separation into small fractions could take place before the solvent front had passed the protein. There was therefore no tendency for the solvents to flow inwards and recombine the fractions; hence the greater number of fractions observed at the end of a run. For a similar reason the protein stayed with the front and did not lag behind.

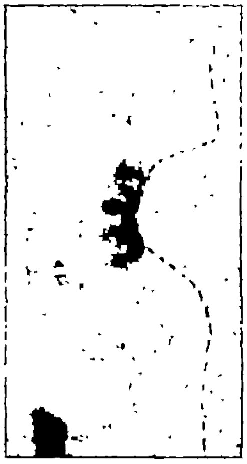

Fig. 3. Photograph of chromatogram obtained with 'Tween 80' and hæmin in the absence of any proteins. Solvent in both directions, *M*/100-fructose. Similar results are obtained with other combinations of solvents

There is therefore no reason for believing that the separate spots observed by Franklin and Quastel should be considered as individual chemical entities. Indeed, chromatograms of a mixture of the emulsifying agents 'Tween 80' or 'Tween 81' and hæmin without any protein produce an essentially similar pattern of spots (Fig. 3). Therefore, the inclusion of this type of compound may well increase the number of spots solely on its own account.

The conclusion to be drawn from this survey is as follows: during flow on a sheet of filter paper, the resistance of protein to transport in aqueous solution, coupled with the ease with which the solvent may by-pass the protein, will always tend to minimize the effectiveness of any possible separation of similar protein species.

The separation of proteins of quite dissimilar nature by this method, however, is, of course, perfectly practicable, as has been shown by Gross, Leblond, Franklin and Quastel[7]; but the patterns observed in complex mixtures such as serum are so dependent on the conditions of the experiment as to be pure artefacts. Given adequate control, there is no doubt a good degree of reproducibility; but owing to differing interactions between various components of different mixtures, the patterns observed can have no direct correlation with the complexities of the mixture.

Since this work was completed, Swingle and Tiselius[8] have also expressed the opinion that the patterns observed under these conditions are artefacts dependent on the general properties of proteins in contact with paper; but owing to the fact that our observations may be of interest in further work on protein separation, we have felt it desirable that they should be placed on record.

A TECHNIQUE for the two-dimensional chromatography of blood plasmas or protein mixtures on filter paper has been described by Franklin and Quastel[1] which differs in certain important respects from the well-known methods adopted in amino-acid paper chromatography. It was found that the additions of small quantities of surface-active agents such as the 'Tweens' or 'Spans' seemed to facilitate the separation of plasma constituents and extend the protein 'pattern'. The technique adopted at present is to add 'Tween 85' or 'Tween 81' to the plasma and use hæmin as the protein marker. A mixture of an alcoholic solution of benzidine and hydrogen peroxide, made acid with acetic acid, is used for detecting the hæmin. Solutions of sucrose and of sodium potassium tartrate have been selected, after many experiments, as the most suitable developing solvents in the first and second dimensions respectively. The former solution appears to facilitate movement of certain protein hæmin complexes, as well as uncombined hæmin, in the first dimension; the latter solution allows movement of certain protein complexes in the second dimension while preventing movement of uncombined hæmin. There must not be overloading of the paper with protein; usually 0·02 ml. plasma is applied. The technique has been used in the study of blood plasma changes that occur consistently after heparin administration and after single high-fat meals[2] and in investigations of multiple sclerosis[3]. It has also been used profitably in an investigation of the combination between thyroxine and plasma constituents[4], in a study of the breakdown of casein by rennin and of the separation of rennin from crude rennet preparations[5], and in the demonstration of non-specific agglutinins for Brucella in bovine sera[11].

Drs. Hall and Wewalka point out that the upward flow of the plasma proteins from the original spot on the paper consists of a gradual elution by the ascending solvent and conclude "that the relative positions of the components of a mixture are dependent on certain factors not necessarily functions of its complexity". They also state, without giving the experimental evidence, that at no stage in the process is there a linear distribution of the various components, albumin and globulin bands appearing in the final electrophoresis patterns of all the areas of the spot (no surface-active agents were used). Thus, they intimate that no separation of protein constituents of the plasma takes place in the first-dimensional run. This conclusion leads them to imply that the fractionations seen in the second dimension are due simply to the mechanical or physical factors operating in this technique, and do not reflect any separations of a chemical nature. It is further claimed that the action of surface-active agents is only to prevent the coalescence of fractions which is observed in the second-dimensional run when no surface-active agent is present.

If these observations and conclusions are correct, it follows that the protein patterns of various plasmas should offer no great dissimilarities, since the patterns are allegedly not dependent on the chemical complexity of the plasmas but on the physical factors operating in the runs in the two dimensions.

Much experience has shown that the protein patterns obtained using our technique with normal plasmas are very similar to each other and may be reproduced with considerable regularity. On the other hand, the patterns obtained with many pathological plasmas differ very greatly from those given by the normal. These may also be duplicated with regularity in the same patient, so long as the clinical condition of the patient does not alter. There is now ample evidence which, it is hoped, will be published shortly, to show that the abnormal patterns observed in certain diseases revert to normal when the disease is successfully treated. Photographs of typical paper chromatograms of (*a*) normal plasma, (*b*) plasma of a patient suffering from cancer of the

stomach, (c) plasma of a patient suffering from lupus erythematosus are shown in Fig. 1 (see also ref. 6, where further results are presented). These facts, pointing to extensive differences between the patterns of normal and pathological plasmas, make it obvious that the nature of the two-dimensional pattern must be a function of the chemical composition of the plasma.

That the physical factors operating in this form of paper chromatography help to determine the final pattern need scarcely be said, and this, it seems to us, is inevitable. But this fact does not justify the conclusion that the pattern does not reflect the chemical composition of the plasma or protein mixture. Moreover, no statement has been made in our publications that the fractions seen in the paper chromatograms of plasmas represent separate protein species.

Definite separations of proteins are practicable by this technique. For example, cytochrome *c* may be separated from serum albumin in a mixture of these substances[illegible]. The former moves but little in the first dimension and is easily taken into the second dimension, whereas the latter moves freely in the first dimension, to the head of the advancing front, and also moves easily in the second dimension. It can be shown (see Fig. 2) that widely different patterns occur with purified preparations of serum albumin, α- and β-globulins, γ-globulin and fibrinogen using our technique. Papastamatis and Wilkinson[7] have also recently demonstrated the different rates of movement of insulin, fibrinogen, γ-globulin and serum albumin, on filter paper using salt solutions as developing solvents.

The paper chromatogram of a mixture of serum albumin, serum globulins and fibrinogen in the proportions in which they are present in plasma gives a pattern very similar to that obtained with a normal plasma (see Fig. 2). This is a further indication that the chromatogram of a protein mixture is dependent on the chemical composition of its constituents.

Hæmin alone, in the absence of added proteins, under our experimental conditions gives but little movement in the second dimension, and this is negligible compared with the movement of the protein–hæmin complexes (see Fig. 1). Drs. Hall and Wewalka point out that movement of hæmin, in the absence of added proteins and in the presence of 'Tweens', does take place in the second dimension; but they use a fructose solution as developing agent in *both* dimensions. Naturally, in such circumstances, a movement in the second dimension will take place; but this is quite irrelevant since they do not use our developing solvent, which suppresses the movement in the second dimension.

Furthermore, Drs. Hall and Wewalka assert that the action of the surface-active agents is due to a 'wetting-out' phenomenon whereby the fractions obtained in the first direction are not allowed to coalesce in the second. Thus, the appearance of greater fractionation is observed. But this assertion does not take into account the fact that, in the absence of the surface-active agent, serum albumin will ascend wholly to the head of the paper, there to be separated into a few fractions in the second dimension[illegible], whereas in the presence of suitable quantities of a 'Tween' the rate of movement of the protein is depressed and a considerably lengthened spot is obtained in the first dimension, giving rise to an increased number of fractions. With a serum globulin, the presence of the 'Tween' may suppress all movement in the first dimension (see Fig. 2).

Combinations of detergent and enzyme proteins have been described[illegible] and it is known from the work of Putnam and Neurath[illegible] that albumins combine with surface-active agents such as the detergents to form complexes of various mole ratios. It is therefore likely that the elongation of the protein spot in the first dimension may be partly due to the different rates of solution of the surface-active agent – protein complexes and partly due to the varying affinities of these complexes for the cellulose of the paper. The increase, therefore, in the number of fractions is probably largely due to the formation of these complexes. There can be little doubt that complex formation between globulins and surface-active agents, such as 'Tweens', also occurs and that these complexes move with great difficulty in the first dimension under our experimental conditions. Use of other surface-active agents may provide for more effective separations of albumins and globulins than we have been able to obtain so far.

Further experiments[illegible] have shown that the admixture of γ-globulin to human plasma brings about a marked alteration of the pattern, a heavy basal fraction appearing when 'Tween' is used. The heavy fractions at the bottom of the pattern seem to be typical of the chromatograms obtained in plasmas of

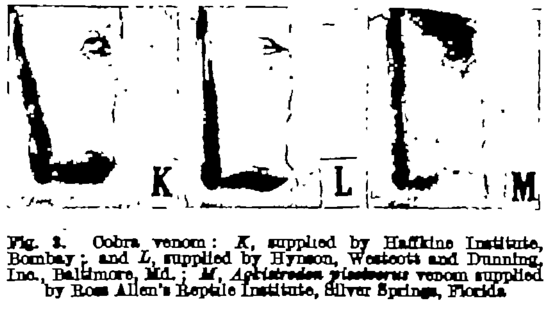

Fig. 3. Cobra venom: *K*, supplied by Haffkine Institute, Bombay; and *L*, supplied by Hynson, Westcott and Dunning, Inc., Baltimore, Md.; *M*, *Agkistrodon piscivorus* venom supplied by Ross Allen's Reptile Institute, Silver Springs, Florida

pathological cases where the globulin/albumin ratio has been increased. It has already been pointed out[1] that the chromatogram of the plasma of a horse immunized against diphtheria toxin (the plasma presumably having an increased globulin content) differs from that of normal horse plasma by the possession of extra fractions at the bottom.

The fact that protein mixtures of different chemical composition yield different patterns is also illustrated by the photographs given in Fig. 3. These show chromatograms of two different samples of cobra venom and of a sample of *Agkistrodon piscivorus* venom, the same quantity (0·8 mgm.) being taken, and no surface-active agents being present. It will be observed that the chromatograms of the two cobra venoms are very similar to each other but differ from that of the other venom.

It is difficult to reconcile two statements in Drs. Hall and Wewalka's communication, namely, "The separation of proteins of quite dissimilar nature by this method, however, is, of course, perfectly practicable", and "the patterns observed in complex mixtures such as serum are so dependent on the conditions of the experiment as to be pure artefacts". We readily agree that all patterns are dependent on the conditions of the experiment; but since separations of proteins admittedly do occur by this technique, the patterns cannot be regarded as solely dependent on the physical conditions and therefore as pure artefacts.

With reference to the suggestion of Swingle and Tiselius[10] that the chromatograms may be "artefacts", we are informed by Dr. Swingle[12] that the evidence referred to in their paper was rather circumstantial and did not seem to justify publication without additional experiments.

Further investigation, especially of a quantitative nature, is needed to decide the chemical nature of the fractions obtained in the second dimension, and such work is now in progress. But ignorance of this fact, at present, need not deter further development of the technique, which is obviously in an exploratory stage. It is possible that it will provide an inexpensive means of clinical aid both in diagnosis and in following treatment.

ANNUAL EXHIBITION OF THE ROYAL PHOTOGRAPHIC SOCIETY, 1951

THE ninety-sixth annual exhibition of the Royal Photographic Society was opened in London on September 13 for one month and will also be shown at the City Art Gallery, Aberdeen, during November 3–24. The exhibition is divided into five groups: pictorial, record, Nature, medical and scientific photography, with a total of 908 exhibits.

The scientific entries constitute the smallest individual group; but medical and surgical entries are well represented. There is a collection of some nine full-sized radiographs in this latter section, one of which is very effectively shown as a two-colour radiograph by D. Stevenson Clark and entitled "Bas relief colour radiograph of right pneumothorax". This was prepared from the original radiograph by contact-printing a positive to give a magenta image and registering this with a solarized negative coloured cyan. One of the other monochrome radiographs, by R. M. Leman, was given a distinct relief effect presumably by the use of a slightly out of register negative mask, which resulted in a noteworthy emphasis of the arteries shown in this particular exhibit. Among the medical prints is one from Manchester Royal Infirmary, in which the arteries of a heart are well revealed by a radiograph made after injection of lead phosphate. Included in the several examples of ophthalmic photography are two, one by P. N. Cardew and the other by Miss A. E. Milne, in which an annular electronic flash tube was used to illuminate the eye. The reflexion of the tube itself by the outer surface of the cornea indicates whether any imperfections exist on this surface, these being revealed by distortion in the shape of the annulus. Two exhibits by D. M. Kermack showing stages in the dissection of a marine worm provide an illustration of how revealing and orderly a careful example of this type of work can be. A series of photomicrographs by G. C. Lenney on cell division in a mouse tumour must have caught the eye of any who have visited the Festival of Britain Science Exhibition, where a large section is devoted to cell division: in these photographs both normal double-cell division and abnormal multi-cellular division showing stickiness of the chromosomes are well shown.

The most interesting exhibits in the science section are those submitted by the National Physical Laboratory. In one of these there is an example of the use of the Linnick interference microscope, in which the relief effect shown on the surface of a photographic negative of a three-bar resolution test object is examined. Horizontally, the magnification is × 2,100; but by virtue of the optical interference shadows an effective vertical magnification of × 166,000 is achieved. The actual relief effect in the gelatin of the image under examination is seen to be almost one micron. The Laboratory also shows some examples of the *Schlieren* patterns produced by high-velocity air flow. Thus the air flow in the neighbourhood of a supersonic jet is shown, as are the pneumatic disturbances produced around an aerofoil at high subsonic and also supersonic speeds. The shock wave produced in the former case and the 'bow wave' in the latter are clearly indicated. By using the properties of polarized light, the degree of air compression in these waves can be assessed by measurement of the interference colours, as is shown in a pair of colour transparencies. Brown–Firth Research Laboratories present what must have been a very difficult subject to photograph satisfactorily, namely, the surface of molten chromium–molybdenum steel at 1,600° C. in a Siemens open-hearth furnace. Several ordinary aerophotographs are shown; but there is no doubt that the stereo-viewing of this type of exhibit as shown by Hunting Aerosurveys, Ltd., is much more impressive, particularly to those unfamiliar with the viewing of this type of photograph. The exaggerated relief effect emphasizes even slight contours, and ordinary two-dimensional photographs of this type of subject seem all the flatter by comparison.

The photographic recording of a collection of examples of mechanical engineering submitted by H. C. Lane also illustrates the value of the stereoscopic record compared with that of the ordinary paper print, although it must be remembered that, in a series of this type, the stereophotographs, being transparencies, are likely to excel the prints in quality by virtue of their extended optical density-range quite apart from the three-dimensional effect. Among the more interesting record photographs must be mentioned those of Lost John's Cave, Leck Fell, Lancs, by J. Benjamin, who, with the aid of an illustrated plan, follows up several regions of this cave, which contains 4,000 yards of passages, by a series of photographs. In the record section, a Royal Photographic Society Medal has been awarded to J. H. Steer for his photograph of a "Tablet", and perhaps the "Chair Back" of Miss J. W. Robinson and the "Royal Festival Hall" by Miss Margaret Harker should also be mentioned among many fine examples.

The largest part of the section on Nature is devoted to pictures of birds, of which the owl seems to be the most popular. Special mention is due to W. E. Higham for a fine series of pictures entitled "Golden Eagle".

UNIVERSITY OF OXFORD

NEW DEPARTMENT OF BOTANY

THE new building of the Department of Botany in the University of Oxford was formally opened on October 8 by Lord Rothschild, chairman of the Agricultural Research Council.

The first professor of botany in the University was appointed by Charles II in 1669. The early teaching of the subject was associated with the Botanic Garden which had been founded in 1621, and buildings for the study of botany were erected during the seventeenth century just outside the Garden wall. Extensions were made to contain the library and herbarium of William Sherard as a condition of his endowment of the chair of botany; but these buildings were removed at the end of the eighteenth century and an orangery was used for housing the library and herbarium. This orangery was incorporated in the professor's house, built by Daubeny in 1836. Daubeny also built a lecture room which was joined to another orangery, altered to hold the Fielding Herbarium, presented to the University in 1851. These two orangeries within the Garden wall were the starting-points of the two separate buildings which, until now, have accommodated the Department of Botany. Further additions were made up to 1933 by new construction and by the lease of the adjacent laboratories of Magdalen College.

The history of the Department meant that its buildings were separated from the other scientific Departments of the University and were unsuitable for the modern study of botany. Soon after Prof. T. G. B. Osborn was appointed to the Sherardian chair in 1937, the University therefore decided to transfer the Department to a new building in the Museum area, although this meant separating it from the Botanic Garden. Sir Hubert Worthington was appointed as architect and the major plans were begun in 1939; but building was held up by the War.

The new building is situated on the south side of the University Parks, behind the Observatory and between the Departments of Pathology and Physical Chemistry. It is united to the new Imperial Forestry Institute by a lecture theatre. The building has a steel frame, reinforced concrete floors and exterior walls of Bladon and Clipsham stone. There are four floors with a total area of nearly 40,000 sq. ft. and the flat roof is available for experimental work.

The teaching of the Department is carried out in three laboratories for advanced study and one for elementary study. The elementary laboratory is designed for a class of 102 in a room that can be comfortably controlled by the demonstrator. There is a small lecture room as well as the large theatre shared with the Department of Forestry. Research is accommodated in large laboratories for plant physiology and mycology and others for ecology and cytogenetics. In addition to private laboratories for the staff, there is also a number of research rooms for one or two workers and rooms for special apparatus. All the main laboratories have their own ancillary rooms for preparing and storing material and apparatus. In one of the northern wings the Fielding Herbarium, the Druce Herbarium (which was formerly kept in its founder's house in north Oxford) and the Forest Botany Herbarium (which used to be kept in the old Imperial Forestry Institute) are collected into two large rooms. Another room contains a small museum and the ancient herbaria. The main store rooms in the basement are served by ramps from street-level and by a lift to all floors and the roof. The departmental library of some fifteen thousand volumes is housed mainly in two stack rooms, except for the collection of taxonomic works which is kept with the herbaria. The reading room contains the Sherard Library and other valuable old books in glass-fronted cases, and is attractively furnished in unstained oak. The furniture and fittings throughout the building have been designed for flexibility and economy in the use of space. Wall benches are supported on cantilevers wherever possible and cupboards and drawers are in interchangeable units. The main services are carried in flues; as well as gas, water and A.C. lighting and power lines, there are 100-volt and 6-volt D.C. circuits in most research rooms; compressed air and fresh air are piped to some benches.

A garden courtyard has been laid out between the new building and the Imperial Forestry Institute and there is a small plot on the north side and a greenhouse on the roof available for growing plants for experimental purposes. The Department will, of course, continue to depend upon the Botanic Garden for much of its material.

RESEARCH AND DEVELOPMENT IN BRITISH COLONIAL TERRITORIES

THE survey "The Colonial Territories (1950–51)"*, as in previous years, provides much of the background against which the value of the work of the Colonial Research Council and like bodies is best appreciated; the present report includes a chapter on research and surveys which summarizes progress reported more fully in "Colonial Research, 1950–51". Meanwhile, the establishment during the year of a Scientific Council for Africa South of the Sahara, which held its first meeting in Nairobi in November, is noted, and also the holding in June of a review conference to survey the work of the Commonwealth Agricultural Bureaux Organization. Progress in starting the work of the various Colonial fishery stations and institutes continues to be hampered by the shortage of qualified staff, and special stress is laid on the opening of the Sugar Technology Laboratory at the Imperial College of Tropical Agriculture. The Colonial Products Advisory Bureau completed ninety-five laboratory investigations and dealt with 672 inquiries. The year saw the formal opening on January 31 of the West African Institute for Trypanosomiasis Research, with laboratories and installations at Kadua and Vom in Northern Nigeria. Construction of a central Trypanosomiasis Research Institute in East Africa has been agreed upon by the East African Governments and the Secretary of State for the Colonies, and it is expected that the whole of the capital expenditure and about 50 per cent of the recurrent expenditure for the first five years will be met from the Colonial Development and Welfare vote.

Although details of the actual scientific work are reserved for the report on "Colonial Research", major developments are appropriately reviewed in the wider context of the present report. This review thus helps to correct some of the criticism which is directed against British Colonial policy; that is also true of other activities of direct interest to the scientific worker which are recorded in the chapter on "The Social Services". Educational developments are discussed elsewhere, but reference may appropriately be made here to the developments recorded in mass education, which show how the organization of government is being adjusted to fit in with the new conception of community development, notably in Kenya, Uganda and West Africa. Where the formation of community development departments or appointment of community development officers has led to village communities being encouraged to co-operate in numerous small projects to prevent flooding or desiccation of the land, reclaim land, construct buildings, eradicate hookworm or roundworm, much has been done to improve the welfare of the community. Steady progress is reported in the medical and health services, and as general standards of public health improve it is becoming easier to select for attention in a particular territory those diseases which have the greatest social and economic significance. On January 1, 1951, there were, however, still 160 vacancies for medical practitioners in Colonial territories, the need being particularly urgent in West Africa and Malaya. The development of health centres in urban and rural areas is gaining in popularity and proving effective. The mobile maritime dispensary service in Sarawak was augmented, and marked success was achieved by the mobile health unit serving twenty-five villages in a remote part of Cyprus. Medical field units, or epidemic control units, which deal with endemic diseases of all kinds in their areas, and also when necessary with epidemics of smallpox, cerebrospinal meningitis, relapsing fever and trypanosomiasis, have been evolved in West Africa from the former Sleeping Sickness Control Units, and their scope has recently been extended to include health surveys.

Arrangements were made during the year with the Pasteur Institute in Paris for freeze-dried B.C.G. vaccine to be supplied to all Colonial territories which require it, but much research is required before the value of universal B.C.G. vaccination can be finally assessed. On the whole, very satisfactory results have been obtained in the treatment of leprosy with sulphone preparations, particularly with diphenyl sulphone.

In the field of malaria, an international conference held in Uganda in November–December under the joint auspices of the World Health Organization and the Commission for Technical Co-operation in Africa made apparent the important contribution in research which could be made in British Colonial territories. At Ibaro in Nigeria the effect of residual spraying in a hyper-endemic area is being carefully studied; a campaign in British Honduras was intensified, when spraying of about 98 per cent of the dwelling houses in the Colony with an emulsion of DDT was completed, and the first phase of the Mauritius eradication scheme—spraying of houses with residual insecticide—was also completed during the year. Increased attention was given to the control of onchocerciasis in African territories—for example, by attacking the small biting fly (*Simulium*) which carries the disease—and it is hoped to eradicate the fly from that part of the Nile where work is in progress on the Uganda hydro-electric scheme by aerial spraying with DDT.

As regards subordinate staff, the main emphasis is still on the training of hospital assistants, male and female nurses, and health inspectors; but laboratory technicians and pharmacists are also being trained and the development of specialist services is accompanied by some specialization in training. Owing to staffing difficulties, Colonial territories could not take full advantage of the offer of the National Association for the Prevention of Tuberculosis, and only two of the six scholarships for training in tuberculosis work in Great Britain were awarded.

Organized efforts to improve nutrition are an essential part of the campaign for raising the level of health, and a feature of practical nutrition programmes is the increased use of food-yeast. Reference is also made in this report to the important part played by broadcasting in education and in assisting the understanding of public affairs, and to the invaluable work in these territories of the British Council. The dependence of social welfare and social services on economic development is made clear, and the report is as useful a contribution to the discussion of economic or political developments in these territories as it is to the consideration of the scientific or technical work which is reviewed more fully elsewhere.

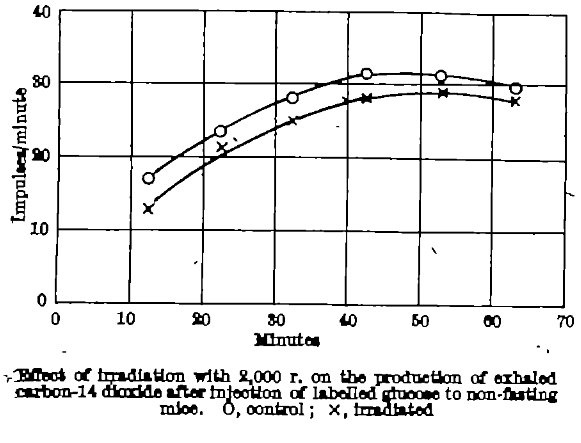
Effect of Irradiation by X-Rays on the Exhalation of Carbon Dioxide by the Mouse

It has been shown previously that the rate of formation of deoxyribonucleic acid is depressed by a sublethal dose of X-rays. Both the incorporation of phosphorus-32 [1-4] and that of carbon-14 [6,7] was found to be reduced about 50 per cent. The rate of incorporation of carbon-14 into the purines of ribonucleic acid is reduced as well[7], though to a smaller extent than its incorporation into the purines of deoxyribonucleic acid. These blocking effects are presumably due to inactivation of enzymes involved in the synthesis of the deoxyribonucleic acid and ribonucleic acid compounds. One or a few days after irradiation, the incorporation of carbon-14 into purines of deoxyribonucleic acid has nearly returned to the rate for the non-irradiated controls. This suggests that a partial reactivation has occurred. The early metabolic changes produced by irradiation are not confined to interference with nucleic acid synthesis. We find that irradiation interferes with glucose metabolism as well.

Fully grown mice which had been fed *ad libitum* were placed in perforated metal boxes which prevented gross movement. In each experiment four such boxes were symmetrically placed in a metal cylinder containing carbon dioxide-free air and kept at 27°. Exhaled carbon dioxide was swept from the brass cylinder by carbon dioxide-free air at constant velocity and collected in a series of three wash-bottles containing barium hydroxide. At intervals of 10 min. the air stream was switched over to another aggregate of wash-bottles. The carbon dioxide was collected for one hour.

Glucose (60 γ having an activity of 0·03 μC.) labelled in all its carbon atoms was injected subcutaneously into each mouse immediately after irradiation. Collection of carbon dioxide started 8 min. after injection. The increase in weight of barium carbonate with increasing time shown in the graph has no significance, as it is a result of the fact that the content of exhaled carbon dioxide in the metal cylinder increases with time. We wished only to determine the ratio of carbon dioxide exhaled by irradiated and control mice, not the total amount exhaled.



Effect of irradiation with 2,000 r. on the production of exhaled carbon-14 dioxide after injection of labelled glucose to non-fasting mice. O, control; ×, irradiated

We found that the non-fasting irradiated mice exhale only some 80 per cent of the amount of carbon dioxide exhaled by control mice. This result does not necessarily prove an impaired catabolism of body glucose. Since only about one-half of the exhaled carbon dioxide originates from catabolism of glucose[8], the other half having its origin in catabolism of fatty acids and other body constituents, it may be that the catabolism of the last-mentioned compounds and not that of glucose is responsible for the reduced exhalation of carbon dioxide by the irradiated mouse. The fact, however, that if labelled glucose is administered the irradiated mice exhale a smaller amount of carbon-14 labelled carbon dioxide than the controls proves unambiguously that irradiation depresses the glucose catabolism of irradiated mice. The graph indicates that the depression is already apparent after the lapse of 8 min. and may possibly be still more pronounced at an earlier time.

It is of interest to note that Lourau and Lartigue observed that addition of glucose to the diet of the guinea pig increases its radiosensitivity[9], that irradiation with 500 r. produces hyperglycæmia in the irradiated animal[10] and, quite recently, that 12–15 days after irradiation glycogen formation in the liver is reduced 1–2 hr. after feeding glucose[11].

The reduced catabolism of glucose in the irradiated mouse is reflected in an increase of forty to one hundred per cent in the carbon-14 content of liver fats.

The Philippine Trench and its Bottom Fauna

Very little is known about animal life in the greatest ocean depths; only two previous hauls seem to have been made below 6,000 metres. In 1899 the U.S. Fish Commission steamer *Albatross* obtained siliceous sponges in the Tonga Trench at 4,173 fm. or 7,632 metres[1]. A similar deep haul was not made until 1948 when the Swedish Deep Sea Expedition trawled holothurians, a fragment of a polychæte, an isopod and a few amphipods in the Porto Rico

Trench at depths between 7,625 and 7,900 metres[2]. I can now report that in July the Danish Deep Sea Expedition of 1950–52 in the research ship *Galathea* obtained living animals of several phyla from a depth of greater than 10,000 metres in the Philippine Trench, more than 2,000 metres below previous known occurrences.

The Philippine Trench is considered to be the deepest area of the oceans of the world. The area of the Trench at 10,000 metres or more was readily delimited with the supersonic echo sounder on board the *Galathea*. Although no real survey of the Trench was aimed at, the soundings necessary for the biological work indicate a continuous area between 9° 04′ N., 127° 05′ E., and 10° 41·3′ N., 126° 37′ E., that is, about a hundred nautical miles long, while the width probably never exceeded about two nautical miles. The greatest depth was found to be 10,540 metres, corrected according to Matthews[3]. This was recorded on July 23, 1951, at 12.50 hr. at 10° 23·8′ N., 126° 40·5′ E. The depth of 10,800 metres recorded by the German cruiser *Emden* was sought for in vain; our soundings were in general agreement, however, with those of the Dutch research ship *Willebrord Snellius* and the U.S.S. *Cape Johnson*, the last-named of which recorded a maximum depth of 10,497 metres[4]. The general direction of the bottom area was about 340°, thus pointing about 20° W. of north. The bottom itself is very even, consisting of a very fine clay with an admixture of sand, small stones, vegetable debris and chitinous remnants of terrestrial insects. A sample of 26 litres was taken with the 0·2-sq. m. Petersen grab from 10,395 metres, besides two cores 75 cm. long with the Kullenberg corer. The temperature at 10,123 metres was 2·56° C., while the minimum temperature of 1·59° C. was found at 3,500 metres.

A three-metre wide sledge trawl of the Agassiz type brought up in the first haul from 10,462 m. an abundance of clay with several stones. The first animal seen was a small white actinian attached to a stone; further search gave altogether some twenty-seven actinians, seventy-five holothurians (*Myriotrochus* sp.), five bivalves (*Portlandia* ?) and one amphipod. The Petersen grab contained one specimen of the same species of *Myriotrochus*. The total result obtained, including one haul with the sledge trawl from 10,417–10,484 m. and another from 10,026 m., was about forty actinians, five echiurid worms, eighty *Myriotrochus*, one elasipod holothurian, five bivalves (*Portlandia* ?), one of each of two species of amphipods and one well-preserved specimen and three fragments of two species of tanaids. This gives altogether nine species, to which undoubtedly more could have been added. But two typhoons passing north of the area made further operations impossible. The skilful manœuvring of the ship, commanded by Captain Sv. Greve, R.D.N., and the very special equipment for deep-sea trawling, were decisive for the positive results. Trawling in other trenches and deeps will be tried in the near future to add material for comparison.

Prof. Claude E. ZoBell, of the Scripps Institute, University of California, has secured live samples of bacteria from the bottom deposits and is keeping cultures on board under his special high-pressure technique.

The proof that a variety of animals have been adapted to life under a pressure of more than 1,000 atmospheres must lead to a renewed consideration of many problems in physiology and biochemistry. The living bacteria may yield valuable material for experiments to solve them.

Composition and Structure of Yeast Cell Walls

IN a study of the structure of the cell wall of baker's yeast with the electron microscope, one of us (A. L. H.) obtained results which induced us to start microchemical work on the presence of chitin (P. A. R.) and to study X-ray diffraction of the cell walls (D. R. K.).

In baker's yeast the main cell-wall material, which remains after successive treatments with dilute alkali and acid, is a glucan[1–4] with links of the 1 : 3 and 1 : 2 β-type. Cellulose has not been found in the cell walls of yeast.

The presence of chitin in several species of yeast has been claimed on the grounds of both the isolation of glucosamin and the chitosan iodine test[5,6]. So far as the Endomycetaceæ is concerned, this has been corroborated by X-ray diffraction; but in other yeasts, including *Saccharomyces cerevisiæ*, no chitin could be detected with this method[7].

In purified cell-wall material from baker's yeast a small amount, ± 0·5 per cent, of nitrogen has been found[1,3,4], which has been interpreted as an impurity. However, the amount is sufficient to account for an admixture of chitin up to ± 7 per cent. In fact, I. Hoette[8] obtained chitosan sulphate crystals from many species of yeast, including *Saccharomyces cerevisiæ*. Although in several species the crystals could not be obtained, chitin was supposed to occur in all of them but in varying and sometimes non-demonstrable amounts.

As to our microchemical work, we could mainly confirm Hoette's conclusions, since chitosan sulphate crystals could be obtained from baker's yeast and from all yeasts tested, including some species which had given negative results in Hoette's experiments. So far, we have encountered only one possible exception. In addition, our results suggest that the amount of chitin in yeasts may increase with the age of the cultures.

On electron micrographs cell walls freed from cytoplasm and cell inclusions by grinding, washing and centrifugation generally appear smooth and without a clear structure. After boiling in dilute alkali, a network of thin fibrils is discernible locally, especially in scars from buds. They seem to be embedded in non-fibrillar material. After subsequent boiling in 2 per cent hydrochloric acid a very striking, coarse network of aggregates of rather short fibrils is shown.

These changes are reflected in the degree of crystallinity as deduced from X-ray diagrams. Native cell-wall material, obtained as mentioned above, generally produces three to four broad and partly weak diffuse rings.

After the alkali treatment the diffuse rings become stronger. In yeast species sufficiently rich in chitin, there appear in addition one or two sharper interferences corresponding to the strongest chitin lines. After the subsequent acid treatment, all interferences become more intense and the diffuse rings are partly resolved into several sharper lines.

With cold 30 per cent hydrochloric acid the chitin could be extracted selectively; this treatment caused the chitin lines to disappear, but left the pattern of other lines unchanged. It does not effect any visible change in the electron micrograph.

There is little doubt that we have obtained the submicroscopic picture and the X-ray powder diagram of the insoluble yeast glucan mentioned earlier. Apparently, in the native membrane the substance is mainly amorphous, or possibly forms part of an amorphous complex of cell-wall constituents linked by easily hydrolysable bonds.

Details of our investigation will be published elsewhere[9].

The work has been supported by the Netherlands Organization for Pure Research (Z.W.O.).

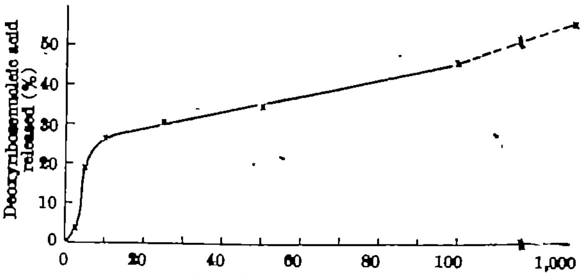
Effects of Ionizing Radiations upon Isolated Deoxyribosenucleoprotein Fibres

CHANGES in chemical and physical chemical characteristics of deoxyribosenucleoprotein and deoxyribosenucleic acid in solution following exposure to ionizing radiations have been described by several investigators[1-3]. Decreased viscosity and chemical decomposition have been reported.

Recently, we have carried out similar experiments using deoxyribosenucleoprotein in fibrous form and have found marked changes at relatively low radiation dosages.

Deoxyribosenucleoprotein was prepared from rabbit liver and calf thymus following the method of Petermann and Lamb[4]. Immediately prior to irradiation, the protein solution in 1 *M* sodium chloride was diluted with 6 volumes of distilled water at *p*H 6·8, producing the characteristic fibres; these, now suspended in 0·9 per cent sodium chloride solution, were subjected to ionizing radiation produced by a stream of electrons from an 800-kV. peak, resonance-transformer type cathode-ray machine. The control samples were prepared in identical fashion.

Following irradiation, the samples were centrifuged for 10 min. at 5,000 r.p.m. The clear supernatant fluid was assayed for nucleic acid by ultra-violet absorption at 2600 A. in a Beckman spectrophotometer, for deoxyribosenucleic acid by the Stumpf colorimetric test[5] and for protein by a quantitative biuret test[6].



Production of soluble deoxyribosenucleic acid by ionizing fibres of deoxyribosenucleic protein at *p*H 6·85

It was found that, following irradiation, variable amounts of nucleic acid had gone into solution (see graph). The biuret tests for proteins in the supernatants were negative.

No significant change in this effect was observed by varying the hydrogen ion concentration from *p*H 5 to *p*H 8. The addition of 0·005 *M* hydrogen peroxide to the deoxyribosenucleoprotein in *M* sodium chloride instead of the distilled water produced no change without irradiation; and subsequent exposure of this mixture to ionizing radiation was followed by changes identical with those without hydrogen peroxide.

In another experiment, deoxyribosenucleoprotein fibres were frozen at −20° C. during exposure. This procedure appeared to protect the fibres, since no deoxyribosenucleic acid was found in the supernatant fluid, indicating that the above-mentioned process takes place as the result of a chemical or 'indirect' reaction.

From these observations it appears that an important change occurs in the deoxyribosenucleoprotein fibres as a result of exposure to ionizing radiations. This decomposition may be related to the chromosome changes seen in cell nuclei following similar exposures.

Because of the radiomimetic action of the nitrogen mustards, we placed deoxyribosenucleoprotein fibres in varying concentrations (0·00064–0·0000064 *M*) of methyl *bis* (β-chloroethyl) amine hydrochloride, but found no evidence of decomposition even after allowing the fibres to remain in these solutions for 18 hr.

We are now carrying out experiments designed to study the effect of lowered oxygen tension, reducing agents and other chemical compounds upon the decomposition of the deoxyribosenucleoprotein fibres; we shall report detailed findings elsewhere.

Nature of the Striated Muscle Fibre Membrane

At the present time, considerable confusion exists as to what should properly be called the sarcolemma, or true muscle fibre membrane. Long[1] defined the sarcolemma as a bipartite structure consisting of an inner layer, the true plasma membrane, and an outer layer composed of reticular fibrils. Meyer and Bernfeld[2] concluded that the sarcolemma is a collagenous-type protein. Jones and Barer[3] failed to find evidence of a collagenous or fibrillar structure.

Cytochemical tests have been carried out on the sarcolemma of isolated muscle fibres of the frog, *Rana pipiens*. In the process of teasing out fibres from various leg muscles, retraction clots were formed in the protoplasm. These clots shrank away from the sarcolemma, thus exposing large areas of the free membrane. The Withrow Morse[4] test for collagen was applied to fifty muscle fibre fragments as well as to entire muscle and bundles of fibres. The sarcolemma in the isolated fibre fragments invariably gave a negative response for collagen. In the whole muscles and bundles a positive reaction was obtained. In the second test for collagen (Chittenden[5]) muscles were boiled in a solution containing dilute sodium hydroxide and nitric acid. Numerous wrinkles, crevices, and folded edges appeared in the sarcolemma. The latter appeared to be festooned along the outer edges of the fibre. These festoon-like areas probably resulted from the swelling effect of the dilute acid. The third test, that of Barer[6], involved digestion of the fibre material in a 0·15 per cent solution of crystalline trypsin at *p*H 7·8. As a control, ligaments, tendons and other collagenous tissue were used. After digestion for four hours the sarcolemma had ruptured and gone into solution. The control tissues were unaffected by trypsin, even after eight hours in the enzyme solution. The xanthoproteic and ninhydrin reactions for protein were applied to the sarcolemma. A positive result was obtained in both tests. In the xanthoproteic reaction, the colour intensity of the sarcolemma decreased as the concentration of the nitric acid was lowered. Lipids were tested for by means of nile blue sulphate and sudan III dyes, with alcohol–ether extracted fibres serving as controls. Positive tests for lipid in the sarcolemma were indicated in both cases.

Bairata[7] regards the sarcolemma as a network of collagen fibres imbedded in a homogeneous colloidal matrix. He states that he has seen fine fibrils within the sarcolemma under polarized light and dark-ground illumination. This could not be substantiated here, nor could fibrils be seen using a phase-contrast microscope. What Bairata possibly considered a collagenous network in the membrane may in reality be the areolar connective tissue investing the individual fibre. Meyer and Bernfeld[2], using the dye methyl red, and Reed and Rudall[8], using the electron microscope, appear to have demonstrated the presence of collagen in the sarcolemma. The latter authors were able to demonstrate collagen fibrils; however, when the optical level of the true sarcolemma was reached, they found it to have a dotted, rather than a fibrillar, make-up. Barer[6] attempted to digest isolated portions of sarcolemma with the enzymes hyaluronidase and collagenase, but without any obvious effects. Jones and Barer[3] failed to find any evidence of a collagenous or fibrillar structure. They found, as did Reed and Rudall, numerous small dots present within the sarcolemma.

Typically, in the present investigation, a positive reaction for collagen in the sarcolemma was always obtained when whole muscle or bundles of fibres were used. When individual fibres, free of endomysium and other connective tissue, were tested, collagen was invariably absent. Furthermore, the sarcolemma always gave positive tests for protein. Unlike collagen, it proved digestible by trypsin. These facts, together with the positive reactions for the presence of lipids, suggest that the sarcolemma is a protein, possibly a lipoprotein. This type of chemical constitution is in agreement with that of the classical object of plasma membrane chemistry, the mammalian erythrocyte envelope.

Transamination in the Human Tooth

In previous communications[1,2] it was shown that the presence of free aspartic and glutamic acids could be demonstrated in carious but not in sound dentine. With the view that a knowledge of the metabolic processes in the sound tooth might aid in an understanding of the caries process, it was decided to investigate whether the sound dental tissues exhibited any enzymatic activity towards aspartic and glutamic acids as substrates.

Using a paper chromatographic method[3], it has been demonstrated that a transaminase occurs in the human tooth in dentine and pulp tissue. This enzyme catalyses the reaction:

$$\text{L}(-)\ \text{aspartate} + \alpha\text{-ketoglutarate} \rightleftharpoons \text{L}(+)\ \text{glutamate} + \text{oxalacetate} \quad \ldots \quad (1)$$

Weaker activity was also demonstrated for the reaction:

$$\text{L}(+)\ \text{alanine} + \alpha\text{-ketoglutarate} \rightleftharpoons \text{L}(+)\ \text{glutamate} + \text{pyruvate} \quad \ldots \quad (2)$$

Owing to the very real technical difficulties involved in working with such small amounts of starting material, it has not been possible as yet to isolate relatively pure active preparations of the enzymes. However, anaerobic incubations using crude extracts and tissue suspensions have been made, and preliminary quantitative studies carried out successfully. The optimum *p*H for reaction 1 is 7·5 and Q_t values for pulp tissue are in the order of 10–12. Studies on the rate of glutamic acid formation, compared with the associated aspartic acid decrease, indicate a greater formation of the former than can be accounted for by loss of aspartic acid. This problem is at present under investigation.

Fuller accounts of this work will be published elsewhere.

Our thanks are due to Prof. E. Matthews, in whose Department the work is being carried out, for help and advice.

Amino-acid Composition of Crotoxin

THE first snake-venom prepared in the pure crystalline form was crotoxin from *Crotalus terr. terr.* as described in 1938; at that time only its cystine and methionine contents were quantitatively determined[1]. This protein, with a molecular weight of 30,000[2], proved to be homogeneous[3] in the ultracentrifuge[3] as well as by electrophoresis[4].

We hydrolysed each time 10 mgm. recrystallized crotoxin in 10 ml. of 6 *N* hydrochloric acid (five times redistilled) for 18 hr. at 120° in closed glass tubes. After removal of the acid in the usual manner, the mixture of amino-acids was analysed by paper chromatography.

The two-dimensional chromatogram on Whatman paper No. 1 with *n*-butanol + acetic acid (40 vol. *n*-butanol, 10 vol. glacial acetic acid, 50 vol. water) in the first, and phenol saturated with water at room temperature in the second, dimension is shown in the accompanying figure.

The following amino-acids could be identified:

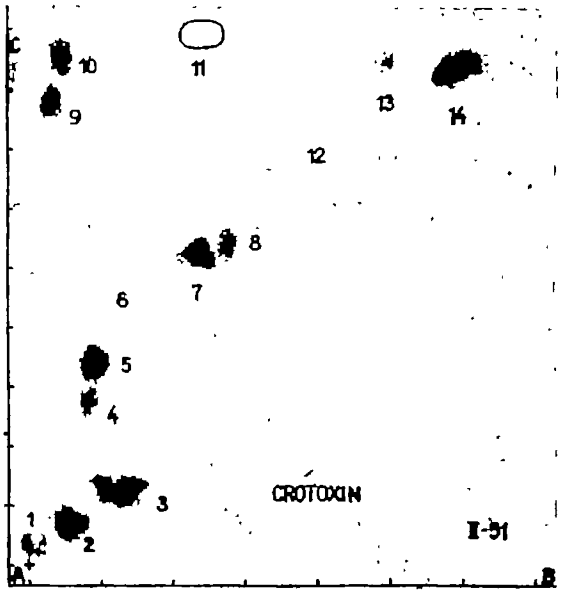
(1) Cystine
(2) Aspartic acid
(3) Glutamic acid
(4) Serine
(5) Glycine
(6) Threonine
(7) Alanine
(8) Tyrosine
(9) Lysine
(10) Arginine
(11) Proline
(12) Valine + methionine
(13) Phenylalanine
(14) Leucine + *iso*leucine

The identification of these amino-acids was checked by control experiments with mixtures of pure amino-acids under identical conditions.

It is known that valine + methionine (12) and leucine + *iso*leucine (14), when using the above-mentioned solvents, do not separate in the chromatogram. We therefore carried out two parallel one-dimensional chromatograms at pH 8·4 with *m*-cresol[5]: one with the crotoxin hydrolysate, the other with a mixture of pure valine and methionine. This showed clearly that valine as well as methionine are present in the hydrolysate.

Two one-dimensional chromatograms in *n*-butanol + benzylalcohol[5] run in parallel, one with a mixture of leucine and *iso*leucine, showed that these two amino-acids are both present in the hydrolysate.

The determination of histidine proved difficult at first. Although we could detect traces of a colour spot with ninhydrin in a one-dimensional chromatogram on Whatman paper No. 1 (using the *n*-butanol – acetic acid mixture), no sign of this amino-acid appeared in the two-dimensional chromatogram (see figure). We therefore ran another one-dimensional chromatograph, on Whatman paper No. 3, which makes it possible to apply larger amounts of hydrolysate and still obtain a good separation.



Hydrolysate of 150 μgm. crotoxin applied at +. Run with butanol + acetic acid in direction *A* → *B*, then in direction *A* → *C* with phenol in an ammonia atmosphere; Whatman paper No. 1

The existence of a small quantity of histidine in the crotoxin was proved by the following procedure: two chromatograms of the hydrolysate were run under identical conditions and developed, one with ninhydrin, the other with consecutive sprays of sodium carbonate and diazotized sulphanilic acid solutions. By means of this reaction (Pauly), the two red spots characteristic of histidine and tyrosine were found.

To detect hydroxyproline, one-dimensional chromatograms of hydrolysates of 100–200 μgm. crotoxin in buffered *m*-cresol were run on Whatman paper No. 1 and 3; neither with ninhydrin nor with isatin[6] were we able to detect any trace of hydroxyproline. From the molecular weight of 30,000[2] it can be computed that, if only one molecule of hydroxyproline is included in the crotoxin molecule, hydroxyproline would represent 0·4 per cent of the crotoxin. But even with amounts of hydrolysate corresponding to 1,000 μgm. of crotoxin on Whatman paper No. 3, it was not possible to detect any trace of hydroxyproline, either with ninhydrin or isatin, although control experiments showed that 3–4 μgm. hydroxyproline are easily made visible in this way.

As tryptophan had already been determined in crotoxin[7], we did not examine any alkaline hydrolysate.

A recently published paper[8] describes the electrophoretic separation of the neurotoxic part of the venom of *Crotalus terr. terr.* By hydrolysation and two-dimensional paper chromatography, the presence of fifteen amino-acids was established; the results differ from ours in that arginine, histidine and valine were not found.

Summarizing our results we can now assert, beyond any doubt, that crotoxin contains the following eighteen amino-acids: arginine, histidine, lysine; aspartic and glutamic acid; phenylalanine, tryptophan, tyrosine; glycine, alanine, valine; leucine, *iso*leucine; proline; serine, threonine; cystine, methionine.

We are indebted to the Instituto Pinheiros, São Paulo, which generously provided crude rattle-snake venom for our experiments.

Tyrosinase and Polyphenoloxidase; the Role of Metallic Ions in Melanogenesis

SOME years ago it was suggested that the first step in melanogenesis, the oxidation of tyrosine to *o*-dihydroxyphenylalanine, can be represented by the following general reactions:

(1) *o*-dihydroxyphenol → *o*-quinone → intermediate products → melanin;
(2) *o*-quinone + monohydroxyphenol + H_2O = 2 *o*-dihydroxyphenol;

and that of these reactions only the first is really enzymic[1].

The apparent different specificity of enzymes of animal and of vegetable origin towards monohydroxy- and *o*-dihydroxy-phenols has led me to re-examine the possible role of metallic ions in the enzymic oxidation of *o*-dihydroxyphenylalanine and of tyrosine.

In this work the copper-free protein of potato-polyphenoloxidase was used, prepared in a manner similar to that described recently[2]. The total reaction volume in each Warburg flask was 2·5 ml.; this included 0·25 ml. of enzyme (corresponding to 15 enzyme units as defined by Lerner *et al.*[3]), varying amounts of metals (between 0·00005 and 0·0016 millimol. in presence of phosphate, and between 0·00005 and 0·02 millimol. in presence of citrate buffer) and the substrates (in side-arms).

I found, in agreement with Kubowitz[4] and with Keilin and Mann[5], that copper is strictly specific and cannot be replaced by any other metal as the prosthetic group of the enzyme. Once the enzyme is saturated by the relatively small amount of copper which it requires, it becomes fully active towards catechol and *o*-dihydroxyphenylalanine (reaction 1), and this activity cannot be augmented by excess of copper or of any other metal. However, I found that reaction 2 between *o*-quinone and tyrosine, that is, the oxidation of tyrosine, is catalysed by free and non-protein-bound metallic ions. Here, there is very little specificity: cobalt, nickel, vanadium and copper are all active, though copper is about 2·5 times as active as the other three. Iron, zinc, chromium, manganese and magnesium are inactive. Vitamin B_{12} appears to be inactive, or not more active than the cobalt which it contains, although physiologically it seems to participate in tyrosine metabolism[6]. Cytochrome *c* is not only inactive but also it inhibits slightly reaction 2. It is interesting to note the complete inactivity, in both *o*-dihydroxyphenylalanine and tyrosine oxidation, of zinc, which catalyses specifically the reaction 2-carboxy-2,3-dihydroindole-5,6-quinone → 5,6-dihydroxyindole[7]; the formation of these compounds thus appears even more problematical, or can only be of secondary importance, in melanogenesis[2].

EFFECT OF METALS ON THE RATE OF OXIDATION OF *o*-DIHYDROXYPHENYLALANINE (DOPA) AND OF TYROSINE

Molar concentration	Time (min.) required for half-oxidation of 1 mgm. Dopa	Time (min.) required for half-oxidation of 0·90 mgm. tyrosine + 0·05 mgm. Dopa
0·00002 Cu	9	180
0·001 Cu + 0·00002 Cu	9	40
0·001 Ni + 0·00002 Cu	9	95
0·001 Co + 0·00002 Cu	9	102
0·001 V + 0·00002 Cu	9	109

Although the transformation of tyrosinase in polyphenoloxidase during the purification process has been known for a long time and has given rise to much theorizing[8], this is the first time, so far as I know, that polyphenoloxidase has been transformed into tyrosinase.

Tyrosinase corresponds to the system polyphenoloxidase + *o*-quinone + metallic ions, the latter functioning probably as electron transmitters in the non-enzymatic reaction between tyrosine and *o*-quinone. Consequently it is difficult to see any justification for retaining the term 'tyrosinase', except as a reminder of the fundamental researches of G. Bertrand and H. S. Raper.

Details of this work will be published elsewhere.

Fertilizing Capacity of Spermatozoa deposited into the Fallopian Tubes

IN the natural sequence of mammalian fertilization, the spermatozoa await the arrival of ova in the Fallopian tubes. The time of waiting may vary from 6 hr. (rabbit), 24 hr. (ferret), 20–30 hr. (pig, sheep and cattle) up to perhaps several months (bat)[1]. Since the transportation of sperm from the vagina to the upper part of the tube is very rapid (a few minutes to 6 hr.[1]), and since the number of spermatozoa present at the site of fertilization is very small[1], this time interval is not necessarily for the accumulation of a large number of spermatozoa to ensure fertilization. The following experiment demonstrates that such a period of time in the female tract is required for the spermatozoa to acquire their fertilizing capacity.

Doe rabbits were injected intravenously with sheep pituitary extract to induce ovulation, which occurs about ten hours later. Ejaculated sperm collected with an artificial vagina was diluted about 1 : 10 with Ringer solution containing penicillin. At various intervals before or after ovulation, four to six does were operated on under ether or nembutal anæsthesia. Flank incisions were made, and about 0·03–0·05 ml. of sperm suspension (0·2–1 million of spermatozoa) was deposited into the upper part of each tube through the infundibulum. Care was taken to avoid injury of the tube and the connective tissues. The animals were sacrificed 36–42 hr. after operation. The ova were recovered from the tubes and examined immediately under stereoscopic and compound microscopes. Only regularly cleaved ova, very often with sperm in the zona pellucida or in the perivitalline space, were regarded as fertilized. The results are presented in the accompanying table.

FERTILIZING CAPACITY OF RABBIT SPERMATOZOA DEPOSITED INTO THE FALLOPIAN TUBES AT VARIOUS INTERVALS

Tubal insemin. Hr. before (+) or after (−) ovulation	No. of rabbits	Ovulation points	Ova recovered	
			Total	Per cent fertilized
−2	5	58	40	0
−1	2	14	10	0
+2	5	42	31	0
+4	5	39	34	6
+6	4	49	41	78
+8	5	50	47	55
Controls (mating) −2	2	20	14	43
Controls (mating) +2	1	13	13	100
Controls (uterine sperm) −2	2	20	15	13
Controls (uterine sperm) +2	2	13	12	75

It is quite clear that fertilization occurs when the spermatozoa have been in the tube for six hours before ovulation, which is perhaps the time required for a physiological change in the spermatozoa enabling them to attain fertilizing capacity.

Sperm were observed in the albumen coat of unfertilized ova following tubal insemination shortly before ovulation. Lack of fertilization from tubal inseminations two hours before or after ovulation was not due to a substance in seminal plasma harmful to the ova[2]. When epididymal sperm were employed (one animal in each group) similar results were obtained. Nor was it due to such a substance in the sperm, or to the harmful effects of operational procedures. Control experiments were performed in which tubal insemination, two hours before or after ovulation, was made to does mated with fertile bucks; all control females had ova fertilized.

Fertilization by sperm deposited into the tube two hours before or after ovulation was, however, obtained when the sperm used had previously been incubated in the uterus of another doe. The semen used in this experiment had been recovered five hours after injection into the œstrous uterus.

Hammond[3] has estimated the period for which the ovum remains capable of being fertilized. He obtained an average litter size of 0·2 young from does mated two hours after ovulation. Assuming four hours for transport of sperm, he concluded that fertility of the ovum after ovulation lasted about six hours at the most.

If this estimate is accepted, it would seem that lack of fertility from tubal insemination four hours before ovulation (or later) was due to loss of fertility in the ova before it was gained in the sperm. It may be, indeed, that the time needed for sperm transport is less than four hours and hence, possibly, the maximum duration of fertility of the ovum is also less. If so, sperm deposited in the vagina in Hammond's experiment must, in passing through cervix and uterus, have acquired fertilizing capacity more rapidly than sperm placed, in the present experiment, directly into the Fallopian tube.

On the other hand, if those sperm required six hours to develop fertilizing capacity, the estimate of duration of fertility in the ovum has to be slightly extended. Another possibility is that sperm are 'activated' in the œstrous uterus, but not when that organ comes under the influence of progesterone.

Fertilized rabbit ova[4] and normal pregnancy of mice[5] were observed when sperm was deposited into the tubes. So far as I am aware, no previous experiment for determining the time relationship between the deposition of sperm and ovulation has been reported. The metabolism of epididymal spermatozoa differs from that of ejaculated spermatozoa[6], demonstrating an influence of environment on the physiology of sperm. The present finding indicates a possible physiological change of spermatozoa in the female tract; this may also explain the lack of success of attempts to fertilize mammalian ova *in vitro* with ejaculated or epididymal sperm. Further study may explain aspects of sterility due to incompatibility between the environment of the female tract and spermatozoa.

Birth Coats of Australian Merino Lambs

WITH one exception, little attention appears to have been paid to the birth coats of lambs, despite the great variability which exists and their potential value in selection in practical animal breeding. The exception is the work initiated by Dry[1,2] with the Romney Marsh breed in New Zealand.

Using the South Australian (Bungaree) merino, observations on birth coats were commenced at this College in 1944. Initially the investigation comprised two phases: (*a*) the genetic background of the birth-coat differences, and (*b*) the use of birth-coat characters as an indicator of adult fleece characters. During the past two years, an additional phase has been added, namely, the gross morphology of the fibre types and their relationship to the series of grades used.

Grading is based on the nature of the coat over the lumbar and sacral regions, and is carried out when lambs are 1–4 weeks of age. For recording purposes a series of six grades have been used. Grade 1 represents a fine birth coat in which the locks are arranged in small spiral tufts. The succeeding three grades are based on an increasing abundance of halo hairs, which appear as a long outer coat above the fine and short inner coat. In grade 5 the halo hairs are so dense that there is no obvious distinction between outer and inner coats. Grade 6 is an extreme development in which it is also impossible to distinguish outer and inner coats and in which the fibres are grouped in large spiral tufts.

The study of the morphology of the fibre types and their incidence in the various grades is not yet complete; but it seems certain that the principal types of fibres described by Dry[1] are also found in the Australian merino.

The work of Dry and Fraser (cited by Fraser[3]) suggested that the coarse birth-coat grades of the New Zealand Romney Marsh breed were the result of a single dominant gene. This observation led us to dichotomize the data between grades 4 and 5, and to examine the results on a 'fine' v. 'coarse' classification. It was postulated that the 'coarse' grades were the result of a single dominant gene and that all parents graded 'coarse' were heterozygous. Examination of pedigrees and breeding performance indicated that this latter postulate was quite reasonable. There is evidence that, as mature animals, there has been some selection against the 'coarse' grades; this selection may have been more severe against homozygous dominants. Denoting coarse grades by *Aa* (heterozygotes) and fine grades by *aa*, the accompanying table shows the results of the three possible matings.

Mating	Progeny grading	
	Coarse (*AA* + *Aa*)	Fine (*aa*)
Aa × *Aa*	17	7
Aa × *aa*	69	84
aa × *aa*	6	108

With the exception of matings in line 3, there is good agreement with the single dominant gene hypothesis. The occurrence of 'coarse'-coated progeny from the mating of fine-coated parents at first sight appears to invalidate the postulate. However, such a position could arise either from misgrading of animals or from complications arising from incomplete penetrance and expressivity. As the six individuals and their parents are in grades 1, 2 or 3, misgrading is unlikely to be the cause of the discrepancy. The fact that the six individuals are all progeny of one ram suggests that the latter alternative is more probable, and that this ram, with birth-coat grade 3, had, in fact, a 'coarse' genotype. Fraser[3] records similar discrepancies in the Romney Marsh breed.

Observations to date on the correlation between birth-coat grade and characters of the adult fleece may be summarized as follows. Increasing birth-coat grade is associated with increasing variability of fibre diameter and decreasing number of crimps per inch; but it does not appear to be associated with mean fibre diameter. Under favourable nutritional conditions there is a close association between mean fibre diameter and crimps per inch in the fine birth-coat grades, but a much lower association in the coarse grades. There is a suggestion in our data that this association in the fine grades does not hold so strongly under conditions of poor nutritional environment.

Cultivation of Canine Hepatitis Virus in Embryonated Hen's Eggs and its Subsequent Transmission to Dogs

Virus hepatitis of dogs was described by Rubarth[1] in 1947 in Sweden, and since then a natural epidemic of the disease has been observed in Britain[2]. From the organs of two dogs dying during this epidemic, the infective agent has been cultivated by the inoculation into the yolk sac of embryonated hen's eggs for twelve successive passages, after which it was passaged back to dogs with reproduction of the disease.

Portions of the liver and lungs from the two original cases or, later, parts of the yolk sac and embryo liver were prepared as inocula by grinding with sand and mixing with broth containing 70 per cent inactivated horse serum and 7·5 per cent glucose to make a 10 per cent w/v suspension, and storing at – 70° C. After the addition of 500 units of penicillin and streptomycin per ml., or filtration through a 'Gradocol' membrane of average pore diameter of 640 mμ, 0·2 ml. of the inoculum was inoculated into the yolk sac of 6th-day embryonated hen's eggs. The first-passage eggs were harvested on the sixth day after inoculation and no abnormalities were detected. In subsequent passages, half the four to six eggs inoculated were harvested on the sixth day thereafter and the remainder on the tenth day. In the second passage, one of four embryos died while three of the four showed hæmorrhages in the liver. With succeeding passages the proportion of deaths increased until, during the fifth passage and after, half the embryos died before the tenth day. These eggs were bacteriologically sterile on culture. From the fifth passage also nearly every embryo inoculated showed hæmorrhage and necrosis of the liver, with ascites in some cases. Macroscopically the liver lesions varied from small pale opaque areas near the lower margin to a condition approaching complete necrosis, which microscopically were confirmed as circumscribed or large areas of necrosis with either karyorrhexis or complete disappearance of the nuclei. In the areas in which hæmorrhages were present, there was evidence of necrosis of the wall of small vessels with damage to the endothelial cells. Inclusion bodies were not found.

Material from the twelfth passage was made up as a 2 per cent suspension in serum broth, filtered through a 'Gradocol' membrane of 750 mμ average pore diameter and passed back to dogs by inoculating 0·05 ml. intraocularly under general anæsthesia into two seven-weeks-old greyhound pups born and reared in isolation. The reaction of these animals to inoculation was followed by clinical observations for twenty-one days and by testing for specific antigen and antibodies by Larin's technique[4].

Pup 1 showed no eye reaction, nor any clinical signs of illness for twenty-one days, but the complement fixation test demonstrated the subsequent development of specific antibodies. Pup 2 developed a marked diffuse dense central opacity of both corneas on the third day after inoculation, which decreased slowly without any vascular reaction until the eighth day. From the third to the sixth day the pup showed increasing malaise, reduced food intake and unformed stools, with a rise of temperature of less than 1° F. The dog was destroyed when clinically convalescent on the eighth day. Macroscopically the internal organs were normal, but microscopically the liver showed vacuolation of cytoplasm and loss of nuclei in the centrilobular liver cell columns; no inclusion bodies were seen. Serological examination showed no antibodies in the blood, but the presence of specific antigen was detected in the liver, from which the virus was passaged to a third dog.

Liver from pup 2 stored at − 30° C. for three months was made up as a 10 per cent w/v purified suspension in saline[4] and inoculated into an eight-weeks-old mongrel pup No. 3, injecting 0·05 ml. into each eye and 10 ml. intraperitoneally. The pup developed a diffuse light central opacity of both corneas on the seventh day, which disappeared in 48 hr. without any vascular reaction, coinciding with which was a morning hyperthermia of 103·6°–104° F.; the dog thereafter was normal. Serological tests showed the presence of specific antigen in the blood on the ninth day and the appearance of antibodies from the twenty-eighth day onwards.

The clinical signs of systemic illness produced were mild, but quite definite; a similar syndrome, including the corneal lesions, has been observed in natural epidemics[2] and in experimental infections[3] of canine virus hepatitis. This diagnosis of specific virus hepatitis is supported by the detection of antibodies in the survivor of the first passage (pup 1) and of antigen in the liver of pup 2, and the confirmation of the presence of virus in this liver by the second passage inoculation into pup 3, which afterwards showed clinical illness with specific antigen and antibody in the blood.

These results show that from cases of virus hepatitis in dogs an agent can be grown in embryonated hen's eggs after yolk-sac inoculation, and that material from the twelfth egg passage filtered through a 'Gradocol' membrane can cause the clinical disease in dogs with the occurrence of specific antigen in liver and blood and of specific antibodies in the blood.

Rapid Rate of Turnover of Potassium Ions in Kidney Slices

The steady-state turnover-rate of potassium ions in guinea pig cortex slices *in vitro* was measured by the isotope procedure developed by Krebs, Eggleston and Terner[1]. There is a rapid initial loss of potassium when kidney slices are placed in physiological saline solutions, but if 0·01 *M* α-ketoglutarate is present, the slices reabsorb the lost potassium[1] and maintain the initial concentration during at least the interval from 25 to 35 min. after the start of the incubation. When this steady state had been reached, potassium-42 chloride was added to the medium and the tissue removed either two or four minutes later. Measurements were then made of the radioactivity and the potassium content of tissue and medium with a liquid counter[2] and a flame photometer[3]. Typical results are shown in the accompanying table.

Turnover of Potassium in Kidney Cortex Slices

Guinea pig tissue suspended in 2 ml. bicarbonate saline containing 0·03 *M* glucose and 0·01 *M* α-ketoglutarate. Potassium-42 chloride added after 25 min. preliminary incubation

Incubation time after addition of potassium-42 ions		2 min.
Fresh weight of tissue		240 mgm.
Potassium ions in tissue	before incubation	17·5 μmol.
	after incubation	17·3 μmol.
Potassium ions in medium		12·6 μmol.
Radioactivity of medium	before incubation	5,320 counts/min.
	after incubation	3,680 counts/min.
Potassium ions exchanged		2·8 μmol./min.
Turnover of tissue potassium ions		16 per cent/min.

The turnover-rate (v/b) was determined from the formula[1]:

$$v = \frac{ab}{t(a + b)} \ln \frac{bx_0}{x(a + b) - ax_0},$$

where v is quantity of total potassium passing from tissue to medium, and in the opposite direction, per unit time; a is quantity of total potassium in medium; b is quantity of total potassium in tissue; x_0 is quantity of potassium-42 added to the medium at time $t = 0$; x is quantity of potassium-42 in medium at time t.

The average rate of turnover from eight experiments was 15 per cent/min. This means that an amount equal to the whole potassium content of the cells leaks out, and is absorbed against a concentration gradient, about every seven minutes. This rate of nine times an hour or more than two hundred times a day is the fastest so far found, being nearly twice that in retina[1], four times that in brain[1] and about five hundred times that in red blood cells[4-6].

A full account of this work will be submitted for publication in the *Biochemical Journal*.

Non-adaptive Characters in Evolution

In a recent communication[1], Dr. A. J. Cain holds that we must now accept that there is no evolution of non-adaptive—or neutral—characters in Nature. He holds this on the ground that certain characters that were previously thought to be neutral have been shown to be correlated in distribution with environmental conditions, and may therefore have some selective value. He thinks that selective value should be assumed in all characters until the contrary is proved.

The subject is controversial; many biologists believe that much differentiation, especially of the minor or trivial differences of micro-evolution, is non-adaptive[2]. Also the subject is complex, and not one that can be adequately discussed in letters in *Nature*. But it may be worth while stating some general grounds for not agreeing with Cain's conclusion, even if we were to admit the selective value of the recently investigated characters that he mentions.

I think it is true that the present position is as follows. Wright[3] has given a theoretical basis for belief that non-adaptive evolution is possible under certain conditions. Many biologists accept his theoretical views and believe that the required conditions occur commonly in Nature. So long as no objections generally accepted by biologists as valid are raised against Wright's theory, we cannot, I think, disregard it, though our estimates of the relative importance of adaptive and non-adaptive evolution must in the end certainly depend on observation and experiment. Differentiations in natural populations are exceedingly various and of different genetic types, and unfortunately very few have yet been adequately investigated.

To assume on the evidence of these few investigations that all differentiation is adaptive seems to me unjustified. I believe that we should at present adopt a more cautious attitude. We must, I think, accept non-adaptive evolution as theoretically possible and, until it is shown to play no significant part in natural differentiation, we must give it a place in our general view of evolutionary theory. In the future we may be able to reach a sounder estimate of its importance, and the many biologists who now believe that it plays a significant part may then be shown to be wrong. We cannot now assume that they are. This was the attitude that I tried to adopt in writing the account of evolutionary theory[4] to which Cain refers.

The Interglacial Beds at Hoxne, Suffolk

RECENT attempts by Woldstedt[1,2] to correlate the Pleistocene sequence in south-east England with that in northern Germany are based on the two marine horizons in each area: the correlation of the March Gravel in England with the Skaerumhede Series on the Continent is probably correct on faunal grounds, and the correlation of the Corton Beds of East Anglia with the deposits of the Holstein Sea in Germany is possibly right, though more confirmation is needed from the fossils. Woldstedt's chief difficulty was to fit the three glacial stages of Germany to the four glacial stages found in East Anglia, and this problem turns on the recognition of an equivalent of the Hoxne Interglacial of Suffolk in Germany. It is therefore important to summarize what is known so far of the interglacial beds at Hoxne.

The general geology of the surroundings of Hoxne is well known, consisting of a till or boulder clay made mostly of Bunter and Jurassic material with some chalk and flint, resting on chalky sand and gravel with occasional marine shells and plates of barnacles. This series forms a plateau at about 130–150 ft. above sea-level, and is eroded by the present stream valleys. The freshwater beds at Hoxne have been formed in a hollow in this plateau boulder clay, and all past investigators agree that they are earlier than the erosion of the modern valleys[3–7]. Enlargement of the brickworks in recent decades has exposed sand and stony brickearth overlying the freshwater series, which have been considered as formed under glacial or peri-glacial conditions[6–8].

The freshwater series represents a climatic succession which has been worked out in great detail, and plant remains collected by Clement Reid[5] show that the oldest clay (Bed *E*), resting on the bottom till, was formed in still water in a temperate climate; after this, a lignite Bed *D* was formed, representing an alder thicket; lacustrine conditions were next responsible for a black loam (Bed *C*), with some arctic plants; a cold climate continued, with the formation of peat and thin gravel layers (Bed *B*); and finally, temperate conditions returned during the deposition of the top blue silt (Bed *A*). The whole of these lacustrine and marsh beds were finally covered by the stony loams representing arctic conditions. The freshwater shells from the lacustrine series confirm the evidence of the plant remains, and the pollen analyses from Beds *B* and *A* point to surrounding birch and pine forest during stage *B* giving place to oak–alder forest with elm and lime at the beginning of Stage *A*[7]. Few large mammals have as yet been traced to definite horizons, but mammoth and ? reindeer have been recorded from Bed *B*, and horse, red deer and beaver from Bed *A*. On the evidence we have at present, it is not advisable to consider the cold episode *C* as a separate 'glaciation'.

Unfortunately, these mammals cannot yet be used for long-distance correlations; but the matrix and erratics in the till at the base of the series are identical with those in the Lower Chalky (Lowestoft) Till of this region, and a completely new assemblage of erratics appears in the top glacial or peri-glacial stony bed, which agrees with that in the Upper Chalky (Gipping) deposits in the areas south and west of Hoxne. So far as our present evidence goes, therefore, the bottom glacial deposit at Hoxne is the upper glacial deposit of the sequence farther east in Suffolk[8], and the top glacial bed at Hoxne is contemporaneous with the lower glacial bed at Brandon[9] and in the Fen District[10]. The main erratics from this top bed used for correlation include a lump of orthoclase felspar, olivine-basalts, schistose grits and augen gneiss. These rock-types are unknown in Suffolk earlier than the Gipping glacial horizon. This geological evidence can be summed up by saying that the Hoxne freshwater beds were formed during an important interglacial stage, and that this stage is the second of the three interglacials so far recognized in Suffolk.

This geological dating agrees well with the archæology. Implements have only been found in place in Beds *A* and *B*, and include High Lodge or Clactonian III flakes[7] and Acheulean bouchers or hand-axes. The bouchers were called "Late Acheulean" by Moir; but a recent examination of about thirty specimens, including ten found recently, has shown that none of them is as late as the Final Acheulean of the French classification, and in my opinion should be identified with the "Late Middle" Acheulean at the end of the Swanscombe series in Rickson's pit[11]. This conclusion is based on a combination of characters including the proportion of ovates (30–40 per cent of those examined), thickness in relation to width, number and depth of flake scars, amount of controlled flaking and secondary work and the extent to which tranchet blows were used. Also an unusually high percentage (44 per cent) have twisted edges. Finally, Levalloisian specimens make their first appearance in the Hoxne sequence in the top glacial bed, which helps to confirm the conclusion that the Hoxne interglacial is contemporaneous with Swanscombe but earlier than Brundon.

Light Filters of Coloured 'Perspex'

Light filters of coloured glass and gelatin are in common use for visual and photoelectric photometers. They are satisfactory, on the whole; but the glass filters are easily broken, and those of gelatin require to be mounted between glass to protect them from water. The transparent polymethyl methacrylate 'Perspex' is now obtainable in several colours and in sheets. This material is very tough and difficult to break, but is easily worked, and can be cut with a saw. The spectral characteristics of the different kinds of coloured 'Perspex' are not such as to make them directly usable as light filters in photoelectric photometers, because of considerable transmission in the red and infra-red by those which are violet, blue and green (Fig. 1); but by combining sheets of the coloured 'Perspex' with the Ilford copper red-absorbing gelatin filter 803, a set of nine serviceable light filters, covering the visible spectrum, has been prepared (Fig. 2), and these have been found to be sturdy and almost unbreakable, and well suited to laboratory use.

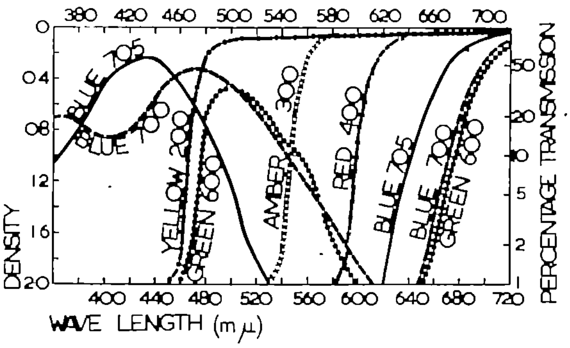

Fig. 1. Spectral transmissions of coloured 'Perspex', ⅛-in. sheets.

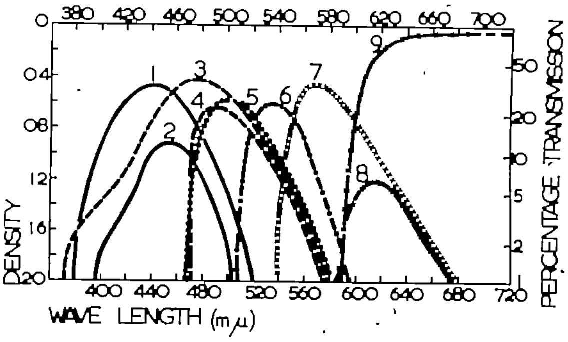

Fig. 2. Spectral characteristics of light filters made from coloured 'Perspex' and Ilford gelatine filter. (See table)

The gelatin filter is placed between two sheets of 'Perspex', either coloured + colourless or of different colours, and the edges bound with 'Perspex' cement, 'Cellophane' tape or gummed paper. The combinations which have been found most useful for photoelectric colorimeters are given in the accompanying table. The 'Perspex' used was cut from coloured ⅛-in. sheet material; and the red-absorbing filter was Ilford sheet gelatin No. 803. Messrs. Allan Industries, Farnham Common, Bucks, prepared the filters for use.

Light Filters of Coloured 'Perspex' and Ilford 803

Final colour	Max. transmission (mμ)	Coloured 'Perspex' No.	Ilford gelatin
1. Violet	440	Blue, 705	803
2. Blue-violet	455	Blue, 705 +blue, 700	803

Solution of Polynomial Equations with the Aid of the Electrolytic Tank

A. Bloch[1] recently extended to complex coefficients Lucas's method[2] of the solution of polynomial equations with the aid of an electrolytic tank. Points of the tank represent complex numbers either directly or after a conformal transformation. In the extended method, sinusoidal currents, in complex vector notation proportional to the residues of a certain rational function with simple poles, are impressed at points corresponding to these poles. Then the points at which the electric field is circularly polarized correspond to the roots of the polynomial equation. The root-points can be found by exploring the tank systematically.

Bloch gave no indication of how his extension could be practically realized. Relevant practical tank measurements[3,4] had been carried out with all electrode currents in phase and one electrode earthed. Consequently the twin-probe assembly which, up to this time, had been used to measure electric field gradients had to be connected to a differential amplifier.

We found that a very satisfactory system of establishing adjustable complex electrode currents can be based on the use of a transformer with a floating and tapped secondary winding. Sets of small numbers of parallel admittances, say six, that are in the ratios 1 : 10 : 100 : $(1 + j)$: $(10 + 10j)$: $(100 + 100j)$, are connected to a limited number of tappings, say, at 0, ± 20, ± 40, ± 60, ± 80 and ± 100 volts. Then any current can be adjusted with an accuracy of 1 in 1,110, any point of the electrolyte can be earthed and an ordinary amplifier and a vibration galvanometer used as detector. A Wagner auxiliary earth eliminates the entry of undesired additional currents at the earthed point. For picking up the gradients in two perpendicular directions a quadruple probe assembly can be used, and it is possible to employ a passive network composed of resistors and condensers that has zero output when the field applied to the quadruple probe assembly is circularly polarized. A passive differential network consisting of a parallel twin-T of resistors and condensers can be designed in such a way that the effects of a maladjustment of the Wagner earth are minimized, so that the Wagner earth requires only occasional adjustment while the tank is explored. Further, it was found that the effect of rotating the quadruple probe assembly when exploring the tank, and injecting in series with the vibration galvanometer a suitable small external voltage, was to make the influence of stray voltages induced in the leads and the amplifier innocuous.

The accuracy of the procedure described can be predicted by mathematical formulæ into which values for the estimated inaccuracy in the setting of the electrode currents and in the positions of the electrodes, as well as the value for the sensitivity of the detector, are substituted. An iterative procedure can be developed which permits the accuracy in determining the roots of polynomial equations to be increased at will.

The quadruple probe assembly can be employed also at a fixed point of the tank, and the current from, or the position of, an additional electrode can be considered the variable by the adjustment of which the field at the probe assembly becomes circularly polarized. This technique makes possible the quick computation of the values of a rational function with given poles for any complex argument. If the rational function has poles of higher order, these can be simulated by simple poles arranged symmetrically around the point in question. The currents to be impressed at these simple poles follow from the coefficients of Laurent's expansion representing an individual higher-order pole by formulæ which are similar to those used in the symmetrical components treatment of polyphase systems.

Theoretical and experimental work has been carried out at the Electrical Engineering Department of the University of Sydney and will be described in the *Australian Journal of Scientific Research.*

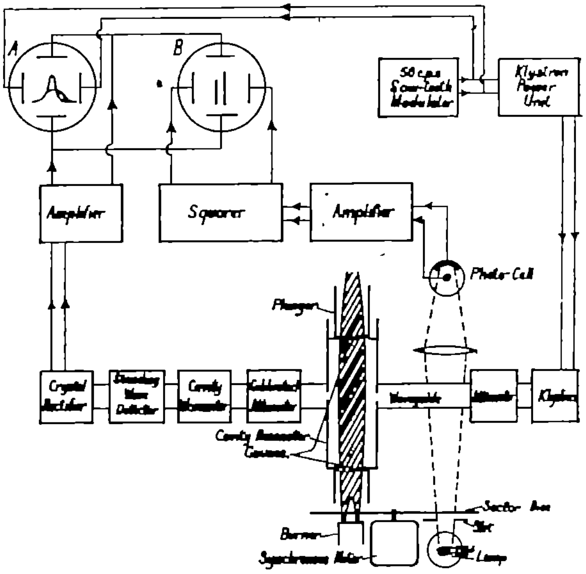
A Cavity Resonator Method for Electron Concentration in Flames

In the course of investigations on the electron concentration produced by evaporation of electrons from the carbon particles in the luminous flames of acetylene and air, it was found that the method of microwave attenuation described by Belcher and Sugden[1] was not sufficiently sensitive. A more sensitive method of obtaining this concentration is to determine the conductivity of the flame by measuring the change in characteristics of a cavity resonator when the flame is inserted in it.

The apparatus (see diagram) consists of a cylindrical water-cooled copper and brass cavity resonator, tuned by a plunger to oscillate in the $(TE,0,1,1)$ mode at about 9,800 megacycles per second. A cylindrical flame passes axially through platinum gauzes, at the base of the cavity and in the tuning plunger. These gauzes consist of radial and circular wires spaced so as to reflect most of the radiation falling on them, without noticeably impeding the flame. Energy from a 723 A/B klystron oscillator, frequency-modulated by a 50 c./s. saw-tooth wave, is fed into the cavity through an iris, and the transmitted energy passes through another iris into the receiving waveguide system, which includes a calibrated attenuator, a cavity wavemeter and crystal detector.



The output of the crystal is applied to the Y plates of two oscilloscopes A and B. The X plates of oscilloscope A are connected to the saw-tooth modulator so that it shows the frequency/amplitude characteristics of the resonator. The most convenient way of taking measurements has been achieved by chopping the flame at 12·5 c./s. with a rotating sector disk, which also interrupts light falling on a photocell, the output of which is amplified and applied to the X plates of oscilloscope B, giving two vertical signals relatively displaced, with amplitudes corresponding to the maximum power transmitted with and without flame; these amplitudes can be compared using the calibrated attenuator. This chopping also serves the useful purpose of preventing distortion and melting of the gauzes by the flame.

In this apparatus the change of resonant frequency of the cavity by the dielectric effect of the flame is small compared with resonance damping due to conduction in the flame, given by the following formula[2]:

$$\sigma = \frac{0 \cdot 00169\, R(t^{1/2} - 1)}{r^2 Q},$$

where σ(mho-cm.) is the conductivity of the flame of radius r cm. in a cavity of radius R cm., and with a Q factor of Q in the absence of flame; t is the ratio of the power transmitted by the cavity in the absence of flame to that in its presence. On the basis of the theory developed by Margenau[3,1], it can be shown that σ is proportional to the electron concentration, the factor of proportionality being sensibly constant under the present conditions and having a value of $1 \cdot 3 \times 10^{16}$. Whereas the direct attenuation method of Belcher and Sugden was only capable of measuring electron concentration to about 5×10^{9} per c.c., the present method is capable of extending this down to about 10^{8} electrons per c.c., that is, a pressure of 2×10^{-8} atmosphere at flame temperatures in the region of 2,000° K.

The flames studied contained about 20–30 per cent of acetylene and gave temperatures ranging from 2,240° to 2,180° K., both by Kurlbaum's method[4] and the sodium line reversal method[5], the cooler and more luminous flames being the acetylene-rich ones. According to a theorem of statistical thermodynamics[6] the number of electrons per c.c. in equilibrium with a solid is given by:

$$n = \frac{2(2\pi m_e kT)^{3/2}}{h^3} \cdot \exp(-\chi/kT),$$

where m_e is the electron mass and χ the thermal work-function of the metal. If the solid is not infinite in extent, however, and consists of N spherical particles per c.c. of mean radius $\bar{r}$, the exponential term will be modified to:

$$-[\chi + f(r)]/kT,$$

where $f(r) = (300\ ne)/(N\bar{r})$ electron volts. Preliminary observations by electron microscopy of the particles have shown $\bar{r}$ to be about 200 A., and theoretical calculation of the amount of carbon indicated 10^{11}–10^{12} particles per c.c., which should make $f(r)$ negligible compared with χ, which is 4·34 electron volts according to Reimann[7].

The results obtained with this apparatus show an electron concentration very near the theoretical value for flames very rich in acetylene, but falling off as the flame becomes hotter and richer in air to values of about one-quarter of theoretical. This is a greater divergence than corresponds with the estimated $f(r)$; but the methods of measurement of N and $\bar{r}$ require further development, and may allow of an explanation of this. The detailed results will be described elsewhere.

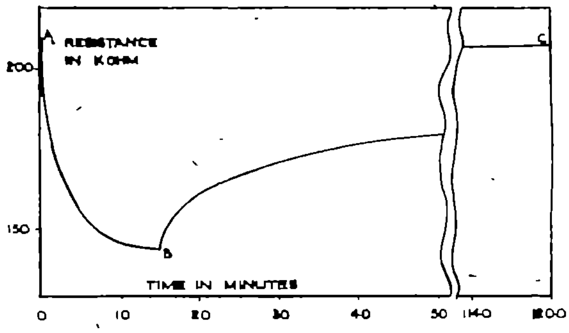
A Photo-conductive Effect in Tellurium Film

IN the course of measurements of the electrical resistance of thin films of tellurium on glass plates, it became clear that the resistivity of a film decreased on exposure to sunlight.

A tellurium film was placed in a dark box for a few days in order to make sure that it was settled in the dark state. Leads through the sides of the box permitted the measurement of the resistance of the film. The lid of the box was then removed so that direct sunlight could fall on the film. It was found that the resistance decreased rapidly at first and then slowly until a steady state was reached after about 15–60 min. exposure to light. The steady-state resistance value depended upon the light intensity but was about two-thirds of the resistance in the dark. On closing the box it was found that the film recovered its resistance value after about a day in darkness.

Measurements were made on a number of films prepared at different times, and in each case the effect was much the same. A typical resistance–time curve is shown in the accompanying graph. It was observed that the speeds of response of the various specimens were quite different even for samples which had been adjacent in the evaporating chamber.



AB, exposed to sunlight; *BC*, recovery in darkness

The speeds of response and recovery were compared by measuring the time taken for the resistance to reach the geometric mean of the initial and steady values. The recovery measurements were the more reliable as it was easier to maintain steady conditions in the dark box than when facing the summer sky. The response times as defined above varied between 2 and 14 min., and the recovery times between 20 and 100 min. There was no simple correlation between the response and recovery times. It will be noticed that the time-scale for this effect is very much greater than for those utilized in the normal photocells, which have response times of a small fraction of a second. It is thought that this effect might be used in photocells required to be insensitive to rapid fluctuations in illumination.

The tellurium films were formed on 3-in. by ½-in. glass slides. Platinum end contacts were deposited on the glass from a solution and fired at 700° C. The tellurium was deposited upon the slide by vacuum evaporation. The film thickness was of the order of 3×10^{-6} cm.

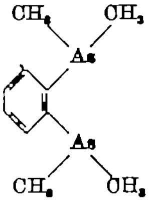
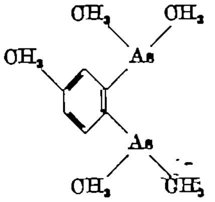
Stereochemistry of Gold

In its complex compounds, tervalent gold appears to be invariably four-covalent, the four bonds being co-planar and pointing to the corners of a square, as in $\mathrm{K[AuBr_4],2H_2O}$ [1]. This suggests the use of $5d6s6p^2$ bonds, which is in accordance with the observed diamagnetism of tervalent gold compounds[2]. The stereochemistry of univalent gold, however, is less well defined. As a rule, the co-ordination number is two, and examples of this include the anion[3] $\mathrm{[AuCl_2]^-}$ and the phosphine complexes of the type $[R_3\mathrm{P,Au}X]$, where X = halogen[4]. In those cases which have been investigated by X-rays, the two bonds to the gold atom are co-linear[5].

In contrast to the behaviour of univalent copper and silver, univalent gold shows a co-ordination number of four only very rarely. Meyer[6] reported a compound of the formula $\mathrm{(NH_3)_2AuCl}$, while Levi-Malvano[7] has described the triethylphosphine complex ammine $\mathrm{(NH_3)_2(Et_3P)AuCl}$. Complex thiosulphates of the type $M^{\mathrm{I}}_3\mathrm{[Au(S_2O_3)_2]}$ are well known[8], but it is uncertain whether the thiosulphate group behaves as a chelate group or is attached through one sulphur atom only; in the latter case the gold atom would be two-covalent. The compound $\mathrm{K[Au(CN)_2,dipyridyl]}$ has been studied by X-rays[9], and it was reported that the gold atom is square co-ordinated; this result is unexpected, for one might anticipate that four-covalent aurous complexes would be tetrahedrally co-ordinated, as is the case for the four-covalent complexes of univalent copper and silver[5]. The subject of the preparation and structure of the four-covalent complexes of univalent gold clearly offers a considerable field for investigation.



I



II

It seemed that the preparation of these complexes should be favoured by the use of suitable strong chelate groups, since the attachment of one molecule of the chelate compound, owing to its shape, prevents the use of linear *sp* bonds and hence might be expected to favour the addition of a second chelate molecule, resulting in the formation of four sp^3 tetrahedral bonds. Using the ditertiary arsine chelate group, *o*-phenylene*bis*(dimethylarsine) (I), a series of complexes of univalent gold, similar to those of univalent copper[10], has been prepared. By treating an alcoholic solution of chlorauric acid with the ditertiary arsine in the presence of a small amount of hypophosphorous acid and adding a little of the corresponding halide, compounds of the general formula $\mathrm{[Au(diarsine)_2]}X$, where X = a halogen, have been prepared. They are exemplified by the bromide, $\mathrm{[Au(diarsine)_2]Br}$, which is obtained as yellow crystals, melting point 226° C. (found, C, 28·0; H, 4·2 per cent; $\mathrm{C_{20}H_{32}As_4BrAu}$ requires: C, 28·3; H, 3·8 per cent). These compounds react with perchloric acid in alcoholic solution to yield the compound $\mathrm{[Au(diarsine)_2]ClO_4}$ as a white insoluble powder (found: C, 27·96; H, 3·8 per cent; $\mathrm{C_{20}H_{32}As_4O_4ClAu}$ requires: C, 27·7; H, 3·7 per cent). This substance decomposes with explosive violence when heated above 300° C. Its salt-like character is demonstrated by the conductivity of its solution in nitrobenzene (molecular conductivity = 28·2 mho at a concentration of $3{\cdot}05 \times 10^{-3}$ molar); the molecular conductivity of uni-univalent electrolytes in nitrobenzene[11] at the above concentration is usually about 20–30 mho. The formation of this perchlorate provides good evidence for the existence of the $\mathrm{[Au(diarsine)_2]^+}$ cation. These aurous compounds are diamagnetic, suggesting the use of $6s6p^3$ tetrahedral bonds. Their physical and chemical properties are being investigated further. Since the ditertiary arsine is strongly attached to the aurous atom, it is proposed to prepare the corresponding gold complexes of the unsymmetrical chelate group (II); if the four bonds to the gold atom are arranged tetrahedrally, it may be possible to effect a resolution into optically active forms, thereby establishing the stereochemistry.

Oxidation of these compounds yields complexes of the type $\mathrm{[Au(diarsine)_2]I_3}$, obtained as dark red crystals, melting point 246° C. (found: C, 21·1; H, 3·1; I, 32·6; Au, 16·9 per cent. $\mathrm{C_{20}H_{32}As_4I_3Au}$ requires: C, 20·9; H, 2·8; I, 33·1; Au, 17·15 per cent). Although this compound could be a perhalide, involving the $\mathrm{I_3^-}$ ion, its properties indicate that the gold atom is tervalent. If this be so, then the cation $\mathrm{[Au(diarsine)_2]^{+++}}$ will be square like the corresponding red diamagnetic nickel ion[12] $\mathrm{[Ni(diarsine)_2]^{++}}$.

A more detailed discussion of the preparation and properties of these compounds will be published elsewhere in due course.

Dipole Moments of Aliphatic and Aromatic Amines

An investigation of the influence of the solvent on the dipole moments of aliphatic and aromatic amines was commenced some years ago[1]; but many of the results have not yet been published. A recent paper[2] has duplicated some of the work of this research. The accompanying table includes a selection of the measurements of the dipole moments of amines, some of which have not previously been determined. In the case of *n*-propyl and *n*-butylamines, the substituted anilines, with the exception of *n*-propyl and ethyl-*n*-propylanilines, and diphenylamine, which were investigated in benzene at 25° by Le Fèvre *et al.*[3], the agreement between the two sets of results is very good. No values of the dipole moments of di-*n*-propyl, tri-*n*-propyl, di-*n*-butylamines, *n*-propyl and ethyl-*n*-propylanilines, and of the other compounds in solvents other than benzene, are available. In the aromatic series, aniline has been studied in solution[1,3] and aniline and dimethylaniline in the vapour state[4].

The polarization at infinite dilution ($P_{2\infty}$), the electronic polarization (P_E) and the dipole moment (μ) in Debye units refer to solutions of the highly purified specimens of the amines in the solvents stated at 20·0° C. No correction is applied for the atomic polarization, and P_E is taken as the molecular refraction for D light of the pure compound.

Amine	Solvent	$P_{2\infty}$ c.c.	P_E c.c.	μ
n-Propylamine	hexane	59·0	19·4	1·38
	benzene	57·3	19·4	1·35
Di-*n*-propylamine	hexane	55·5	33·5	1·03
	benzene	57·1	33·5	1·07
Tri-*n*-propylamine	benzene	59·5	47·7	0·75
n-Butylamine	hexane	62·0	24·1	1·35
	*cyclo*hexane	61·8	24·1	1·35
	benzene	64·5	24·1	1·39
Di-*n*-butylamine	hexane	65·8	42·8	1·05
	benzene	67·3	42·8	1·09
Methylaniline	hexane	96·6	35·7	1·71
	benzene	93·4	35·7	1·67
Dimethylaniline	hexane	92·7	40·7	1·58
	benzene	93·5	40·7	1·59
Ethylaniline (see ref. 5)	hexane	100·2	40·4	1·70
Diethylaniline	hexane	120·8	50·2	1·84
	benzene	120·0	50·2	1·83
n-Propylaniline	hexane	104·8	45·1	1·69
	benzene	104·1	45·1	1·68
Ethyl-*n*-propylaniline	hexane	124·1	54·9	1·82
	benzene	125·2	54·9	1·84
Diphenylamine	hexane	79·7	58·2*	1·02
	benzene	79·9	58·2	1·02

* Obtained from measurements on solutions.

Measurements of the dipole moments of *n*-propyl and *n*-butylamines in the vapour state and in solution in benzene[2] have shown that both these compounds exhibit a positive solvent effect, that is, an increase of dipole moment in solution as compared with the value for the vapour. The present results in benzene confirm, and those in hexane extend, this conclusion.

The increase of dipole moment from ethyl to diethylaniline, which may be compared with the increase from *n*-propyl to ethyl-*n*-propylaniline, is found in both hexane and benzene.

In most of the examples in the table, the dipole moment changes only slightly with the solvent, while in others no differences between the moments are found.

Formula for Creep Curves of Metals

MANY formulæ have been presented for the time-strain curves of metallic creep, among which Andrade's formula[1],

$$l = l_0 (1 + \beta t^{1/3}) \exp (kt),$$

seems to have attracted much attention; but it has not been possible to find a satisfactory explanation of it. Hence we thought it worth while to look for another equation which agrees well with experimental results.

Table 1. POLYCRYSTALLINE COMMERCIAL ALUMINIUM AT 320° C. UNDER THE STRESS OF 1·78 × 10⁸ DYNES PER SQUARE CM.

Time (sec.)	Length observed (mm.)	Length calculated from our formula (mm.)	Length calculated from Andrade's formula (mm.)
7	50·857	50·872	50·465
25	51·429	51·325	51·280
118	53·187	53·130	53·278
439	57·345	57·355	57·468
1,110	64·973	65·010	64·782

Table 2. SINGLE CRYSTAL OF COMMERCIAL ALUMINIUM AT 350° C. UNDER THE RESOLVED SHEAR STRESS OF 8·5 × 10⁷ DYNES PER SQUARE CM.

Time (sec.)	Shear strain observed	Shear strain calculated from our formula	Length observed (mm.)	Length calculated from Andrade's formula (mm.)
95	0·0225	0·0223	50·515	50·438
318	0·0511	0·0471	51·142	51·176
990	0·1122	0·1118	52·568	52·568
3,156	0·2475	0·2521	55·847	55·593
8,040	0·4548	0·4516	61·133	61·515
12,205	0·5886	0·5866	64·728	66·537
19,260	0·7869	0·7946	70·241	75·525

We have carried out extensive experiments on the creep of polycrystals and single crystals of high purity and commercial grade aluminium at elevated temperatures under constant stresses. The constant stress device used was the same as that of Andrade[2] in the case of polycrystalline materials, and was somewhat modified in the case of single crystals to keep the stress constant in the slip direction in the slip plane. After examining all the experimental results, we got the following time-strain equation:

$$s = a - \frac{1}{bt + c} + kt,$$

where s is the resolved shear strain at the time t in the case of single crystals, or the logarithm of the ratio of the length of specimen at the time t to its initial length in the case of polycrystalline materials; a, b, c and k are constants independent of time. If we consider only the transient component, it is readily shown that

$$\frac{ds}{dt} = b(a - s)^2,$$

which is similar to the equation of a second-order chemical reaction. Our equation agrees with the experimental results just as well as Andrade's does in the case of polycrystalline specimens, as shown in Table 1; and it proved to be far better than Andrade's for large strains of single crystals, especially after long times, as is seen from Table 2. Results sufficient to illustrate these points only are included in the tables; full details will be published later.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, October 22

Society of Dairy Technology (in the Lecture Room, New Hall, Royal Horticultural Hall, Greycoat Street, London, S.W.1), at 10.30 a.m.—Annual General Meeting.

British Society for the History of Science (in the Lecture Theatre, Science Museum, Exhibition Road, London, S.W.7), at 5.30 p.m.—Dr. Joseph Needham, F.R.S.: "A Re-valuation of Chinese Astronomy".

Institution of Electrical Engineers (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "The Place of Electricity in a National Fuel Policy" (to be opened by the President).

Society of Chemical Industry, Fine Chemicals Group (at the Royal Institution, Albemarle Street, London, W.1), at 7 p.m.—Prof. A. R. Todd, F.R.S.: "Vitamin B_{12}". (Members of the London Section are invited.)

Textile Institute, London Section (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Mr. K. W. L. Kenchington: "Science of Clothing in relationship to Comfort and Human Efficiency in Cold Conditions".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Prof. Frank Debenham: "The Kalahari To-day".

Tuesday, October 23

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. J. B. S. Haldane, F.R.S.: "Inborn Differences between Human Beings".*

Society for Applied Bacteriology (at the Medical Society of London, Chandos Street, Cavendish Square, London, W.1), at 4 p.m.—Symposium on "The Effect of Cold on Micro-organisms".

University of London (at the London School of Economics and Political Science, Houghton Street, Aldwych, London, W.C.2), at 5 p.m.—Prof. Charles Singer: "Technology and History". (Hobhouse Memorial Lecture.)*

Institution of Civil Engineers, Public Health Engineering Division (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. R. H. MacDonald: "Relation between Daily Rainfall and Flow of the River Shin". (Members of the Royal Meteorological Society are invited.)

Royal Anthropological Institute (at 21 Bedford Square, London, W.C.1), at 5.30 p.m.—Mrs. Elise J. Baumgartel: "Archæology and Earliest Egyptian Religion".

Royal Society of Medicine (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Sir Alan Rowlands: "The Changing Incidence of Disease" (Presidential Address).

Society of Chemical Industry, Chemical Engineering Group (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. G. M. Rowell: "Some Sulphur Recovery Processes in Refinery Operations".

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. E. H. Thompson: "Some Aspects of the Development of Photogrammetric Plotting Machinery".*

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.30 p.m.—Prof. W. T. Astbury, F.R.S.: "The Scientific Basis of Medicine, 5, Studies by X-Ray Analysis, Electron Microscopy and Supporting Techniques of the Structure of Biological Macromolecules and the Tissues Formed from Them".* (Further Lectures on October 25 and 30, November 2, 5, 7, 14, 16, 20, 23, 27 and 29, December 4, 6 and 11.)

Royal Society of Medicine, Psychiatry Section (at 1 Wimpole Street, London, W.1), at 8 p.m.—Dr. Jules H. Masserman (Chicago): "Biodynamics and Psychiatry".

Wednesday, October 24

Eugenics Society (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Prof. Arnold Sorsby: "Prospects in the Control of Genetic Disease".*

Society of Chemical Industry, Nutrition Panel of the Food Group (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.15 p.m.—Dr. R. P. Cook: "The Physiology and Psychology of Alcohol".

Manchester Metallurgical Society (at the Engineers' Club, Albert Square, Manchester), at 6.30 p.m.—Dr. H. O. Smerd: "Recent Developments in Electrically Welded Chains".

Thursday, October 25

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Mr. A. J. Arkell: "The Beginning of Civilization in Egypt".*

Physical Society (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. Frank Twyman, F.R.S.: "Sir Charles Parsons and Optical Engineering" (1951 Parsons Memorial Lecture).

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.30 p.m.—Prof. B. C. J. G. Knight: "The Scientific Basis of Medicine, 6, Aspects of Bacteriostasis".* (Further Lectures on October 30, November 2, 5, 7, 14, 16, 20, 23, 27 and 29, December 4, 6 and 11.)

British Ornithologists' Union (at the Zoological Society of London, Regent's Park, London, N.W.8), at 6 p.m.—Dr. Gustav Kramer: "Orientation Mechanisms of Migrating and Homing Birds".

Textile Institute (at 16 St. Mary's Parsonage, Manchester), at 6.30 p.m.—Herr Hans Locher: "Electronic Sliver and Yarn Regularity Testers".

Friday, October 26

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Geophysical Discussion.

Chemical Society, Newcastle and Durham Section (in the Chemistry Building, King's College, Newcastle-upon-Tyne), at 5.30 p.m.—Prof. A. C. Chibnall, F.R.S.: "Recent Advances in the Chemistry of Insulin" (Bedson Club Lecture). (All Fellows are invited.)

Institution of Mechanical Engineers (joint meeting with the Applied Mechanics Group, at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Mr. W. C. F. Hessenberg and Mr. R. B. Sims: "The Principles of Continuous Gauge Control in Sheet and Strip Rolling".

Manchester Statistical Society, Statistical Methods Study Group (at the Albert Hall, Peter Street, Manchester), at 5.30 p.m.—Mr. D. C. Shaw: "Prices and Margins in the Cotton Industry".

Geographical Association, Manchester Branch (in the Geography Room, Central High School for Boys, Whitworth Street, Manchester), at 6 p.m.—Mr. H. B. Rodgers: "The Oil Industry in the Middle East".

Friday, October 26—Saturday, October 27

Society of Public Analysts and Other Analytical Chemists, Biological Methods Group (at the Medical Society of London, 11 Chandos Street, Cavendish Square, London, W.1), at 2.30 p.m. and 10 a.m.—Symposium on "The Evaluation of Chemotherapeutic Substances".

Saturday, October 27

British Psychological Society, Scottish Branch (in the Psychology Department, The University, Edinburgh), at 2.30 p.m.—Symposium on "The Psychology of Art".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant (Grade A) to teach Mathematics and Physics, and an Assistant (Grade B) to teach Chemistry, in the Department of Science, County Technical College, Wednesbury—The Director of Education and Clerk to the Governors, Dept. F.E., County Education Offices, Stafford (October 27).

Assistant Chemist in the Fuels and Lubricants Section of the Central Laboratory, Chiswick—The Staff Officer, (F/EV.191), London Transport Executive, 55 Broadway, London, S.W.1 (October 27).

Assistant Director (with a good honours degree and research experience, preferably in engineering) in the Central Research Establishment, Stoke Orchard, Cheltenham—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/380 (October 27).

Assistant Experimental Officers (with a degree in engineering or physics, or equivalent) in the Horticultural Department—The Secretary, National Institute of Agricultural Engineering, Wrest Park, Silsoe, Beds (October 27).

Assistant Lecturers (with a degree in mining or engineering, or equivalent)—The Principal, Technical College, Longport, Canterbury (October 27).

Lecturer (with a degree in engineering and good industrial and teaching experience in structural work) in the Department of Engineering, County Technical College, Wednesbury—The Director of Education and Clerk to the Governors, Dept. F.E., County Education Offices, Stafford (October 27).

Lecturer (with a special honours degree in chemistry; industrial or research experience desirable) in the Science Department—The Principal, County Technical College, Stoke Park, Guildford, Surrey (October 27).

Lecturer in Physics (university degree in physics essential) to teach the subject, including Nuclear Physics and Electrons, to Final B.Sc. and Higher National Certificate standard, and an Assistant, Grade B (university degree essential) to teach Physics up to Intermediate B.Sc. standard and some Mathematics, at the Oxford Schools of Technology, Art and Commerce—The Chief Education Officer, 77–79 George Street, Oxford (October 27).

Principal (honours graduate with experience of technical education and industry) of the Wallasey Technical Institute—The Director of Education, Town Hall, Wallasey (October 27).

Senior Clinical Psychologist (with an honours degree in psychology, or equivalent qualification, and experience in clinical psychology)—The Physician-Superintendent, St. John's Hospital, Stone, Aylesbury, Bucks (October 27).

Teacher in the Department of Chemistry and Biology (with a good degree in either biology or chemistry, and qualified to teach the other subject up to Inter. B.Sc. standard at least), Leeds College of Technology—The Chief Education Officer, Education Department, Leeds 1 (October 27).

Technical Assistant in the Department of Agriculture (Fisheries Branch)—The Secretary, Civil Service Commission, 43 Upper O'Connell Street, Dublin (October 30).

Engineering Inspector (Civil Engineering) in the Ministry of Commerce—The Director of Establishments, Ministry of Finance, Stormont, Belfast (October 30).

Biochemist to undertake research and laboratory investigation in connexion with urological disease—The Secretary, Institute of Urology, Henrietta Street, London, W.C.2 (October 31).

Honours Graduate in Physics, mainly for research and development work in the clinical uses of radioactive isotopes—The Secretary and House Governor, Mount Vernon Hospital, Northwood, Middx. (October 31).

Lecturer in Applied Mathematics—The Secretary to Council, Westfield College, Hampstead, London, N.W.3 (October 31).

Lecturer in Land Surveying at the University of Natal, Durban—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 31).

Senior Lecturer in the Department of Civil Engineering, University of Natal—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 31).

Senior Lecturer or Lecturer in Anatomy at the University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (October 31).

Lecturer (with an engineering degree or equivalent qualification, and experience in the engineering and/or process industries) **in Work Study** (method, motion and time study) in the Department of Engineering Production—The Secretary, The University, Edmund Street, Birmingham 3 (November 1).

Assistant Lecturer or Lecturer in Engineering—The Registrar, University College, Cathays Park, Cardiff (November 3).

Scientific Technologist in the Coal Survey Laboratory at Cardiff—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/379 (November 3).

Lecturer in Engineering—The Secretary, The University, Aberdeen (November 7).

Biophysicist (Principal Scientific Officer grade) with first- or second-class honours degree, research experience in general physics and some experience in the application of physics to physiological problems, at the R.A.F. Institute of Aviation Medicine, South Farnborough—The Secretary, Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4077/51 (November 8).

Principal Scientific Officer (Sociologist) (with a first- or second-class honours degree or high qualifications in one of the social sciences, and considerable experience in the use of social survey methods or operational research technique) in the User Requirements Division of the Building Research Station of the Department of Scientific and Industrial Research—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4084/51 (November 8).

Electrical Engineers in the Admiralty—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.210/51 (November 15).

Senior Scientific Officers (2, with a first- or second-class honours degree in botany, and well qualified in systematic botany) **in the Department of Botany**, British Museum (Natural History), for research work in the Herbarium and the identification of plants and plant products—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4083/51 (November 15).

Senior Scientific Officers (4 Chemists and 2 Biologists) in the Forensic Science Laboratories at Birmingham, Bristol and Wakefield—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4085/52 (November 15).

Aeronautical and Mechanical Engineers (Scientific Officer grade) mainly in the Aerodynamics and Structures Departments of the Royal Aircraft Establishment, South Farnborough—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting C.596/51A.

Area Scientist (with a good honours degree and sound experience in fuel technology and coal analysis) in Cannock, Staffs—The Divisional Establishment Officer, National Coal Board, West Midlands Division, Himley Hall, Dudley, Worcs.

Assistant Lecturer (Grade B) **in the Department of Mathematics**, College of Technology and Commerce—The Director of Education, City Hall, Cardiff.

Assistant Technical Examining Officer (male, temporary) **in the Victualling Department** of the Admiralty—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.60/51A.

Chemists (Scientific Officer grade) at a Ministry of Supply research establishment in the South Midlands area, to specialize in a semi-conductor research—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.698/51A.

Chemists, Physicists, Electrical Engineers and **Biologists** at the Tropical Testing Establishment, Port Harcourt, Nigeria: **Senior Scientific Officer** (Ref. A.23/51A) to lead a group of physicists and engineers studying the effects of tropical conditions on service materials and equipment, a **Scientific Officer** (Ref. F.686/51A) to work on analytical or biochemical investigations in connexion with deterioration of equipment under tropical conditions, and a **Senior Scientific Officer or Scientific Officer** (Ref. G.349/51A) to study the biological attack on materials and equipment under tropical conditions—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No.

Civil and Mechanical Engineers by the Ministry of Supply in London, Christchurch, Farnborough, Pendine, Salisbury, St. Helens, Malvern, and elsewhere, for design, development, installation and quantity surveying in structural and plant engineering fields, chemical plant, buildings and plant for aerodynamics and armament research, etc.—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting E.450/51BA.

Electrical Engineers and **Physicists** (Experimental Officer grade) by the Ministry of Supply at experimental establishments near Southend, Carlisle and in South Wales, for work connected with out-of-door instrumentation: **Physicists or Electrical Engineers** preferably with some knowledge of experimental range technique and procedure—for some posts (Ref. A.262/51A) a knowledge of electronics or mathematics is required, and for others (Ref. A.263/51A) experience in design of electronic apparatus and interest in technical photography is desirable, a **Physicist** with interest in chemistry (Ref. A.264/51A), and a **Physicist** with interest in mathematics (Ref. A.261/51A) to examine experimental records obtained during trials—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No.

Electrical and Electronic Engineers by the Ministry of Supply in London, Malvern, Chertsey, Bromley and Sevenoaks, and elsewhere—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2 quoting D.408/51.A.RA.

Engineer III by the Ministry of Supply in Lancashire, to assist in the design and supervise the testing and installation of chemical plant, and the temporary erection and testing of individual units—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting C.607/51A.

Lecturer in Bacteriology—The Assistant Registrar, Trinity College, Dublin.

Lecturer (with a good honours degree and conversant with recent research in the chemistry and physics of rubber and similar polymers) **in Rubber Science**—The Clerk, National College of Rubber Technology, Northern Polytechnic, Holloway, London, N.7.

Mathematicians (Scientific Officer grade) at a Ministry of Supply experimental establishment near Salisbury, for the study of theoretical problems of stability and control and the application of statistics to aircraft testing requirements—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.273/51A.

Metallurgists and **Physicists** (Scientific Officer grade) as leaders in the X-Ray and Electron Microscope Group in the Metallurgy Division of the Royal Aircraft Establishment, South Farnborough—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting A.285/51A.

Pasture Officer, Somaliland Protectorate, to advise the Director of Agriculture and Veterinary Services on technical matters relating to pasture control, to devise and carry out experimental work etc.—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. No. 27059/259.

Plant Pathologists to form a pool from which a plant pathologist can be detailed or seconded to any Colonial territory to undertake a comparatively short-term investigation of any particular problem as required; when not overseas, the plant pathologists would work at the Institute under the Director on the taxonomy of fungi or plant pathological work of importance to the Colonies—The Director Commonwealth Mycological Institute, Ferry Lane, Kew, Surrey.

Scientific Officer in the Department of Marketing and Exports, Nigeria, for research work on problems relating to insect infestation of food products, survey work and experimental treatments of infestation—The Director of Recruitment, Colonial Office Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. No. 27059/297.

Senior Assistant (Scientific) at the Atomic Energy Research Establishment, Harwell, to assist in work with high-pressure apparatus with radioactive materials, with remote handling apparatus, and with high vacuum furnaces—The Ministry of Supply, Est.3.C.1, Room 829.D, Adelphi, London, W.C.2, quoting V.R.703, or the Employment Exchange, Harwell Site Office, Atomic Energy Research Establishment, Harwell, Didcot, Berks, quoting Order No. 185.

Senior Experimental Officer at the Ministry of Supply London headquarters, for duties concerned with research and development of aircraft textile materials in all forms (fabrics, cordages, ropes, etc. and involve technical consultations with industry and research organizations, etc.—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2 quoting F.697/51A.

Senior Experimental Officers, Experimental Officers and **Assistant Experimental Officers** at the Atomic Energy Research Establishment, Harwell: **Physicists** (Ref. A.266/51A), **Senior Experimental Officer** to take charge of, and **Experimental Officer** to assist in, the industrial applications of radioactive isotopes, involving complex techniques; **Chemical Engineers** (Ref. F.670/51A), **Experimental Officers** and **Assistant Experimental Officers** with experience in erection and operation of chemical plant on the pilot or semi-technical scale, or in process development on the laboratory or larger scales; **Chemical and Metallurgical Analysts** (Ref. F.670/51.A.EO), **Experimental Officers** and **Assistant Experimental Officers** for analytical work (two of the posts are connected with the analysis of heavy metals, rare elements and their alloys) **Metallurgists** (Ref. F.669/51A), **Experimental Officer or Assistant Experimental Officer** with experience in heat treatment, to operate small vacuum melting and precision heat-treatment furnaces **Development Engineers** (Ref. C.565/51A), **Senior Experimental Officer or Experimental Officer** for development of special type of plant and instruments requiring remote control or for operation under onerous conditions of temperature, pressure and corrosion, for example, pumps, valves, filters, etc.—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No.

Senior Plant Pathologist (Senior Principal Scientific Officer) at the West African Cocoa Research Institute, Gold Coast—The Under-Secretary of State, Colonial Office, Research Department Sanctuary Buildings, Great Smith Street, London, S.W.1.

Statistician for work on the investigation of the short-term effect of different controlled thermal conditions on the physiological responses and performance of groups of human beings, and a **Biochemist** to carry out work on physiological problems of the adaptation of human beings to hot climates, at the Royal Naval Tropical Research Unit, Singapore—Dr. O. G. Edholm, Medical Research Council Laboratories, Holly Hill, Hampstead, London, N.W.3.

Statistician in the Department of Genetics, to work on problems and methods in genetics and biological experimentation—The Secretary, John Innes Horticultural Institution, Bayfordbury, Hertford, Herts.

Teacher of Telecommunications Engineering—The Clerk Northern Polytechnic, Holloway, London, N.7.

TECHNICAL AND TECHNOLOGICAL EDUCATION IN GREAT BRITAIN

A DISAPPOINTING feature of the fourth report of the Advisory Council on Scientific Policy, the general features of which were discussed in *Nature* of September 22, is its failure to give a clear lead on the question of higher technological education in Great Britain. The contents of the subsequent White Paper on Higher Technological Education are equally disappointing (see *Nature*, September 29, p. 543). Presented to Parliament by the Chancellor of the Exchequer, the Lord President of the Council, the Minister of Education and the Secretary of State for Scotland, it is marked above all by anxiety to avoid giving offence. With an ingenuity which compels the admiration even of those who deplore its shortcomings, it evades all the important issues and contributes nothing to the necessary long-term policy. For the present there is prescribed the mixture as before: the universities will strengthen their existing departments of technology, and one or two may be enabled to expend much more considerably. The civic pride of anything up to sixty-six local authorities will be satisfied by additional financial assistance to their technical colleges, and expansion will begin along lines shortly to be announced.

In a measure, these proposals meet the imperative need for early decision so that the universities and the technical colleges can make their appropriate plans. How far this expansion will meet the real national needs, and above all that to which the Percy Committee directed attention more than six years ago, cannot well be judged until the detailed proposals for making improved financial assistance available for selected technical colleges and courses are made known and until the University Grants Committee announces the results of its examination of the proposals for university expansion, presumably in connexion with its plans for the next quinquennium. Meanwhile, however, a College of Technologists is to be established with responsibilities limited to granting awards and the approval of courses, thus shearing of some of its dangers the ill-considered recommendation of the National Advisory Council on Education for Industry and Commerce.

It is not suggested that the expansion of the university departments of technology and of the technical colleges will not give some useful increase in the number of highly trained technologists as distinct from technicians. That distinction is not made clear in the report, in spite of the recognition that industry needs recruits of a wide range of types, outlook and experience. What is clear from the statement is that university expansion in this field and the expansion of the technical colleges shall continue to proceed independently. The need for one body capable of taking an impartial and a national view is ignored.

This is the first major defect in the proposed policy, and until it is remedied it is idle to talk of using available resources so as to give the best results in the short as well as in the long run, or to make the most appropriate use of existing institutions. No comprehensive and satisfactory national system of higher technological education can be evolved in its absence. Six years ago, the Percy Committee recorded the general view that the position of Great Britain as a leading industrial nation was being endangered by a failure to secure the fullest possible application of science to industry, and that this failure was partly due to deficiencies in education, especially to a shortage of scientific workers and technologists who can also administer and organize, and can apply the results of research to development.

That is the background to all subsequent discussions on higher technological education in Britain, and in his recent book, "The Neglect of Science", Prof. F. E. Simon states that a visit to the United States strengthened his conviction that the most important thing needed to make our industry competitive is the reform of technological education in Britain. Such reform will not be secured by patching the existing system; and, disregarding for the moment Prof. Simon's own preference for at least two new technological institutions of university rank, the first step to a coherent national policy of higher technological education is to make its supervision the responsibility of some one body, whether it is carried out in university institutions or in appropriate technical colleges. If for valid reasons the establishment of a special Technological Grants Committee—a suggestion to which the National Advisory Council on Education for Industry and Commerce gave inadequate attention—is impracticable, the duty should be entrusted to the University Grants Committee with appropriately enlarged terms of reference.

The first essential is a body that can take independent and long views, with authority and standing sufficient to resist sectional pressure. The importance of this condition is at once apparent when we consider the question of the selection, from among the sixty-six existing colleges said to be providing higher technological education in Great Britain, of those which are to receive increased financial assistance. There is no indication as to who is to make the selection or the grounds on which it is to be based. From the national point of view, it is unnecessary and undesirable to upgrade to university status more than about six such institutions. The National Advisory Council in its report suggested that the actual selection should be made after consultation with the regional academic boards, which were established by the Ministry of Education to give advice in the field of technology. There are, however, ten such boards, and it would be optimistic to expect that such boards will take a national point of view and not incline to favour colleges in their own area. Ruthless decisions in favour of a few institutions, in fact, can scarcely be expected of such bodies; but without such ruthlessness there is grave danger that the limited amount of money available will be distributed too widely to make any real improvement anywhere.

The second essential condition for the development of higher technological education in the technical colleges is a matter not of finance but of status. The White Paper fails as completely as the report of the National Advisory Council on Education for Industry and Commerce to show any appreciation on the importance of the question of independent governing bodies and full academic freedom for the selected colleges. The issue is evaded or ignored; but this question of status and of academic freedom is of vital importance.

Unless the selected colleges are able to attract teachers of high standing and ability there is little hope of any real improvement in their status. More generous financial support and the full adoption of the new Burnham awards will be insufficient while the control by local authority and the Ministry of Education remains. Incidentally, it should be remembered that, even if that obstacle were removed, there are insufficient teachers of high calibre available to conduct the requisite courses in more than a fraction of the present sixty-six colleges. Such teachers are unlikely to be obtained unless they can be offered conditions of service fully comparable with those at the universities by removal of the subjection of the colleges to local authority and Ministry.

This question of staff is critical. Unless the difficulty is faced and overcome, the selected colleges will never acquire the status which will enable them to attract students of high quality, and no awards made by the College of Technologists will be comparable with either a university degree or the qualifications of the professional institutions. The proposal for a College of Technologists contributes nothing new and bypasses all the real difficulties. It cannot even be described as putting the cart before the horse, for if the real problems of upgrading a few selected colleges to university level are handled with courage and vision, a new award would be superfluous, just as it will be valueless if those problems are not solved.

Half-hearted solutions which merely avoid difficulties will get us nowhere, and so far as can be judged at present there is to be no real change in policy Some return will be secured from the expansion in the university departments of technology now being made in the universities, but as regards the technica colleges less confidence can be felt. There is real dange that the available resources will be distributed to widely to make any effective contribution anywhere t the provision of technologists of the calibre required and the White Paper gives no indication that th situation will be handled with vision and imaginatio

The White Paper does not, it is true, exclude indefinitely the possibility of a technological university. The proposal is rejected for the present o account of the capital outlay required, and because such a project for an entirely new centre woul involve at least five or six years of planning and building, so diverting large resources required els where and yielding no return in the form of graduate for at least ten years. Even the expansion of a existing institution would involve heavy capital co and building commitments, and here again no rapid return could be expected.

These, and especially the last, are the wron reasons. There are no firm grounds for assumin that in any foreseeable time more resources will favour experiment. The situation is more likely to deteriorate than to improve, as is indicated by the remarks made on October 1 by the retiring vice-chancellor of the University of Cambridge on the financial anxieties of the University in view of rising costs. The most promising methods of reform are usually expensive; but caution and a predilection for ways that have been found wanting are no policy for a nation in difficulties.

It may have been right to reject the idea of founding an entirely new technological university, though the White Paper would have been more convincing had it faced frankly the arguments in its favour, and particularly the danger that expansion of technology in the universities themselves may distort their balance of teaching and research. This problem has already been discussed by Prof. A. R. Ubbelohde and others. Technological research is liable to involve expensive and specialized equipment to a greater extent than academic research, except perhaps in some fields; and we cannot ignore the possible effect on the university departments if expansion takes place in the main at the universities. Equally, whatever expansion is planned at selected colleges of technology must provide for research as well as for teaching, and the same problem, possibly in even greater measure, will arise there also.

We are forced, therefore, to conclude that not only must the expansion of higher technological education in Great Britain be planned by one body, but also that that body must be competent to take account of the work of the research institutes and research associations and to advise on the best location of specialized equipment from the national point of view, having regard to teaching as well as research. Unless this is done, it is idle to talk of the wisest and most effective use of limited resources. It is right that there should be a reasonably wide range in the type of provision to be made for higher technological education: the universities, the colleges of technology, possibly also the research associations and other research institutions have their contribution to make, and, if only on the ground of variety, it is to be regretted that further experiment by establishing a higher technological institution is not to be undertaken.

There is an additional reason, not mentioned in the White Paper, for regretting that decision. In his recent Redwood Lecture before the Institute of Petroleum, on "The Training of a Technologist", Prof. F. H. Garner, professor of chemical engineering in the University of Birmingham, made much the same point as Lord Hankey emphasized in his Centenary Lecture on higher technical and scientific man-power a little more than a month earlier. Both stressed the importance of the technologist possessing certain qualities of character and leadership, and the desirability of providing in his training the conditions which encourage the development of such qualities. It is worth noting that Dr. P. Dunsheath, commenting on his recent visit to the United States as a member of the team sent by the Anglo-American Council on Productivity to study relations between the universities and industry, remarked that industry there also is looking for like qualities, and the universities are seeking to develop them.

There are some pertinent observations on this topic, as well as some useful suggestions, in the Walker Trust Lecture, "The Universities and Cultural Leadership", which Sir Walter Moberly delivered before the University of St. Andrews last February, and in which he firmly maintained that education for social responsibility is still a legitimate and necessary task for universities. Sir Walter denounced as heresy the doctrine that the only business of the universities is to turn out specialists, and the doctrine is no less pernicious when it is applied to the colleges of technology. But what is most significant in the present connexion is not that Sir Walter expressed a view which has been strongly endorsed from the industrial side in recent discussions on higher technological education, but rather his reminder that the universities develop such qualities not merely by requiring their students to submit to the basic intellectual disciplines of mathematics and classics, but chiefly by bringing together teachers and students who represent a wide circle of interests and providing them with a stimulating community life.

There, in short, is a compelling reason for experimenting with a technological university. The stimulus which might be derived from bringing together leading minds in many different technologies in one university centre has been overlooked. This was plainly as much in Prof. Garner's mind as in Sir Walter Moberly's, and such contacts are one means of encouraging the awareness and study of human relationships which Prof. Garner rightly stressed as an essential element in the training of engineers, or of other technologists, who throughout their careers will be concerned with human as well as with technical problems. Moreover, such a centre is in a far better position to dispel the notion which still persists that a career in technology is in some way inferior in status to that in some other professions, particularly if in organizing its courses of study care is taken to avoid keeping them in water-tight compartments.

The segregation of various departments of knowledge in existing university departments is one cogent reason for desiring to experiment with a new institution, without at the same time ceasing to encourage the expansion of some existing university departments of technology or of selected colleges of technology. Part of the value of a new technological institute may well lie, in fact, in its influence on the colleges of technology and the university departments. The graduate schools of technology, for which Prof. Garner pleaded in conclusion, could find their place either in the universities or in the expanded and upgraded colleges of technology, but would probably prove most fruitful in a new institution of the type of the Massachusetts Institute of Technology. Even in present circumstances, with the full support and co-operation of industry, such an experiment should not be beyond our resources; and the indirect results, as well as the technology, should be considered before rejecting such a proposal.

Prof. Garner in his Redwood Lecture recognizes frankly that the techniques of industry are not appropriately taught in a university, nor indeed in a college of technology: they must be acquired in industry itself. In the university or the college of technology, the student should be taught why different techniques are used and the principles on which they are based. If the teaching is at the same time directed to encourage the development of the personalities of individual students, those administrative defects to which, like Lord Hankey, Dr. R. P. Russell, Sir Handley Page and others, Prof. Garner directed attention, are less likely to be in evidence.

Those defects are due primarily to the lack of a balanced outlook on the part of a technologist or scientific worker who is called upon to assume administrative responsibilities. In his book "The Impact of Education on Society", Mr. W. O. Lester Smith suggested three years ago that the right answer to the Barlow Report might be found in a nobler conception of the technical college rather than in a multiplication and expansion of universities. Prof. Garner's Redwood Lecture is only one indication of the extent to which a nobler conception of technological education as well as of the technical colleges marks current contributions to the discussion on higher technological education in Britain. That conception is conspicuously absent from the White Paper. Without it, without imagination, enterprise and the readiness to experiment, neither the formulation of policy nor its execution in practice is likely to meet what is now one of the most urgent needs if the industrial future of Great Britain is to be made secure.

THE TEACHING OF PHYSICAL CHEMISTRY

The Structure of Physical Chemistry

By Sir Cyril Hinshelwood. Pp. viii+476. (Oxford: Clarendon Press; London: Oxford University Press, 1951.) 35*s*. net.

THE presentation of physical chemistry to students presents difficulties to the teacher. Sometimes the subject is broken down into separate chapters and dealt with as a series of specialisms; sometimes various aspects and ideas are taken up as tools to be used in other fields of chemistry; and sometimes the subject is dealt with in a broad sweep of impressionism. All these methods have their own advantages and disadvantages.

It is right that the student should study in detail the important specialized aspects of his subject, so that he may be able to use the tools of physical chemistry sharpened, and with the skill of a good craftsman. But such studies alone tend to obscure the nexus of ideas which connect these specialisms and to lose the threads which run through the subject as a whole.

It is right that as early as possible the student should see the subject as a whole, and should appreciate the position of physical chemistry between physics, concerned with the general principles governing matter, and chemistry, concerned with the individual behaviour of substances and their variety. The young student should, like the children of France, 'speak French well': it is exciting and inspiring for him to use his new-learnt language in other branches of chemistry and to discuss organic reactivity and the manifoldness of inorganic phenomena in terms of the pattern-forming ideas of physical chemistry. But such a broad sweep of ideas —this early speaking of the new language of physical chemistry—may lead to looseness of thought and communication, to lack of rigour and to a false impression of real understanding. Sir Cyril Hinshelwood quotes from Alice: "Somehow it seems to fill my head with ideas—only I don't exactly know what they are".

This problem—this conflict between the synthetic view and appreciation of the subject and detailed and rigorous study—is one which every serious teacher of physical chemistry must face and resolve. The reconciliation of these conflicting ends is in a sense one of artistic presentation. It is an artistic problem; because the subject must be apprehended as a whole, because by touches of the author's brush light and shade must be introduced—the masses of facts, the planes of thought and the tenuous lines of imagination must stand in harmonious relation to one another; and because the work must be stamped with honesty and integrity of thought and understanding. In this sense "The Structure of Physical Chemistry" is a work of art. I would recommend this book to all students of physical chemistry.

The following outline of the scope of the book under notice may indicate the general development of the treatment. The fundamental ideas that matter is made of atoms and molecules, and heat is mechanical motion of atoms and molecules, governed by Newtonian laws, are first introduced. These two ideas, which reached quantitative formulation in the past century, are applied to lead to the numbers and sizes of molecules, their speeds, and the frequency of molecular encounter. The discussion of molecular motion and chaos develops naturally to the introduction of entropy, to statistical mechanics and thermodynamics. Energy at this stage is left as an empirical quantity. But already, very early in the book, the reader has the beginnings of statistical thermodynamics and has heard that most important and recurrent *Leitmotif*—the opposing influences of entropy and energy in chemical equilibrium and change. These ideas are then applied to both physical and chemical equilibria: thermodynamics, statistical mechanics and kinetic theory are used in the discussion, and their essential unities, their various limitations and powers are thus revealed in relatively simple applications.

The furtherance of these questions requires a closer knowledge of the energy states which have already been envisaged in the discussion of entropy; this leads to the introduction of the quantum rules for molecular motion and to the simple evaluation of the partition functions of vibration, rotation and translational motion, and a return to a more detailed discussion of equilibrium and the factors determining its position. But it is not sufficient to accept the energy changes which arise from forces between molecules to give stages of aggregation or, between atoms, to give chemical compounds, as empirical data; and the further investigation introduces the electronic constitution of atoms, the description of states by wave functions and the architecture of atoms and molecules.

The reader is now in a position to be given a more complete discussion of assemblages—of electrons and atoms in metals, of molecules and ions in crystals and in liquids and solutions. He can understand more clearly the ordering effect of van der Waals, Coulomb and valency forces and the opposing effect of random motions. The three fundamental ideas which form the basis of modern chemistry are thus combined: matter is made of atoms, heat is mechanical motion of atoms and molecules, and particles have a wave-like nature.

The equilibrium patterns of chemistry are manifold and varied, but changes of pattern give "vitality and movement to the scene"; and the last section of this book gives a beautiful discussion of chemical changes. Collision theory, transition state theory, thermodynamic analogies, and energy and entropy factors are discussed with clarity, rigour and simplicity; their fields of usefulness in the theory of reaction rates and their limitations are set out. Typical reaction mechanisms are outlined: bond breaking, ionization, atom transfer, electron transfer, energy transfer, chain reactions—and the student is shown how in all these problems our knowledge of valency forces, molecular configuration and motion has made our ideas of chemical changes more precise; and how, here as in equilibrium, ordering into pattern carries with it the concomitant increase of entropy.

This book will give the student the right picture of the subject as a whole; it brings together the various lines of attack, showing clearly their several powers and limitations. It will inculcate rigour of thought and a critical approach—but at the same time will stimulate the student to take up tools which are so attractively presented to him, to sharpen them, and to use them for himself. He will go to his specialist monographs and lectures on thermodynamics, quantum theory or statistical thermodynamics with a proper understanding of their positions and their uses.

The specialist will understand his specialism the better for seeing it set in the subject as a whole.

The research worker will be stimulated to thought and investigation by the problems which are hinted at or are thrown into relief: there is none of the finality of the last word about this book; the inquiry goes on—"that is perhaps the greatest fascination of its adventure".

The book is beautifully written: there are occasional flashes of wit and asides of philosophy—indeed, teaching in its highest form: that sense of intimate conversation with a master. M. G. Evans

---

PURE AND APPLIED CHEMISTRY OF ACRIDINE COMPOUNDS

The Acridines

Their Preparation, Physical, Chemical and Biological Properties and Uses. By Prof. Adrien Albert. Pp. xiii+381. (London: Edward Arnold and Co., 1951.) 70s. net.

THE investigation of acridine compounds has, in recent years, been to a large extent in the hands of Prof. A. Albert and his collaborators, and it is gratifying to know that the considerable experience which they have gained should now be available, with much else besides, in this volume. To the average student of organic chemistry the subject of acridine is all but a closed book, and the present work should dispel any ideas that may be abroad to the effect that the chemistry of acridine derivatives is dull and uninspiring.

The first eight chapters (Part 1) of the book deal with preparative methods for the synthesis of acridines, acridans and acridones, and it is early apparent that the author has written into its pages a wealth of sound practical experience. A number of preparations, either of acridine derivatives or of essential intermediates, are described at the end of each chapter, and the style is simple and direct, although occasionally a laboratory colloquialism replaces the more formal language of the text-book.

Part 2, also of eight chapters, discusses physical and chemical properties of acridines, preparation and properties of substituted acridines, aminoacridines, quaternary acridine derivatives, reduced acridines, acridones, thioacridones and binuclear derivatives. The degradation of substituted 5-aminoacridines in alkaline solution with hydrogen sulphide, noted by Hammick and his pupils, is not specifically mentioned although the reference is given in a misleading context. Apart from this slight criticism, the first two sections of the book are written in a balanced and critically objective manner.

The first chapter of Part 3, dealing with the utilization of acridines in clinical medicine, has been written a little more enthusiastically and somewhat less objectively than preceding and later chapters. Obviously Prof. Albert sees in the acridines a potential source of valuable drugs in addition to mepacrine and the existing aminoacridine antiseptics; for he asks the leading question (p. 234), "Have the possibilities of using acridines in therapy been exhausted ?" and adds, "The answer is most emphatically no", going on to say that ". . . the clinical possibilities of 'the acridines' are potentially as fertile as those of 'the benzenes' (which recently contributed sulphanilamide, p-aminosalicylic acid and chloramphenicol)", although it is conceded "that, as with other nuclei, the acridine ring contributes only a fraction to the biological action of its derivatives". Part 3 continues with a stimulating chapter on chemical constitution and antibacterial action; but the chapter dealing with the antimalarial action of acridine derivatives would have gained somewhat in perspective by even brief mention of chloroquine, which is derived, at least in theory, from mepacrine by ablation of one of the benzene rings.

The remaining chapters of the book cover tinctorial properties of acridines, the connexion between constitution and colour in the acridine series, and fluorescence and chemiluminescence among acridines. The work ends with a really excellent reference and author index, together with a good subject index and an index to the preparations described.

The author is to be congratulated on the completeness with which he has covered his subject and on his ability to write authoritatively and with equal facility on so diverse a range of specialized aspects of pure and applied organic chemistry. Most organic chemists and many biologists will find much to interest them in this volume, and its well laid-out tables, ninety-nine in all, will save many time-consuming searches in the literature for data on acridine and its derivatives. All concerned with the production of this book, author, printers and publishers, may derive satisfaction from the certain knowledge that their work will be gratefully received by a wide range of readers. J. Walker

SPIDERS OF BRITAIN

British Spiders

By G. H. Locket and Dr. A. F. Millidge. Vol. 1. (Ray Society Vol. 135 for the Year 1949.) Pp. ix+310. (London: Ray Society, c/o British Museum (Natural History), 1951.) *27s. 6d.*

SEVENTY years is a long time to wait for a book, and yet Pickard-Cambridge's "Spiders of Dorset", published in 1881, was, until now, the latest attempt to describe all the spiders of Britain. The absence of a recent book of this kind has been felt more and more seriously for more than half a century: now at last help is forthcoming in this the first of two volumes from the Ray Society. It is a work on which the authors, Mr. G. H. Locket and Dr. A. F. Millidge, who speak with the voice of experience and authority, can be unreservedly congratulated.

The opening chapter, a contribution from Dr. W. S. Bristowe, is a historical account of the study of British native species, in which Bristowe appreciatively surveys the work of his predecessors. He happily takes notice of their individual qualities and makes a human story of what might have been a dull record of specialized zoology. Wisely he emphasizes again the fact that nearly all our knowledge of British spiders is due to the devotion of men otherwise engaged on their own professional duties, while the British Museum (Natural History), for more than forty years, has sacrificed spiders to mites.

Mr. Locket and Dr. Millidge have tackled their systematic and descriptive problem in an engagingly workman-like manner. After the customary paragraphs on collecting and preserving spiders, and an account of their external features which is, perhaps, rather longer than necessary, they print a dichotomic key to twenty-four British families, with adequate illustrations and the addition of fifteen very helpful 'notes'. The families follow in turn, each with a summary of its characteristics, a key to its genera, and descriptions of its species.

Diagnostic work of this kind can never produce dramatic writing: a reviewer can but look for the underlying principles and try to judge the help afforded to readers who, less familiar with the animals themselves, are trying to name spiders from these pages. In so doing I find, first, descriptions which emphasize the essentials and are not overburdened with repetition and detail. Blackwall's description in 1861 of the common species *Xysticus cristatus* occupied a thousand words; Locket and Millidge are more practically helpful in two hundred. They tell their readers exactly what to look for in each species, and give accurate drawings of genitalia and other features that they may expect to see. British araneology has never before had anything like this; within its own sphere it is an outstanding contribution to taxonomy.

Because of this it is unfortunate that, while most of the admirable drawings have been clearly reproduced, some have not reached the high standard that we have become accustomed to expect in Ray Society volumes. Fig. 21 (*Ciniflo similis*) is an example of this: the fault lies not with the artist but in the process of reproduction, and is particularly regrettable.

The notes on the distribution of each species are ecological in character, not geographical. Here again, it is on the practically helpful information that the emphasis has fallen. This volume, which covers 205 species in seventeen families, has not reached the Linyphiidae, the most 'difficult' group, but it includes several of the genera in which separation of the species is sufficiently puzzling. One turns to these genera—*Lycosa* and *Clubiona* are examples—with interest, and finds the same practical guidance, the genera being conveniently split into groups and the contrasting characteristics of closely related species displayed in tabular form.

As I have said, this book was badly wanted and has not disappointed me. I look forward to its successor with keen anticipation of even greater satisfaction. T. H. Savory

DYNAMICS FOR MATHEMATICIANS

Advanced Dynamics

By E. Howard Smart. Vol. 1: Dynamics of a Particle. Pp. xi+420. Vol. 2: Dynamics of a Solid Body. Pp. xi+420. (London: Macmillan and Co., Ltd., 1951.) 40s. net each Vol.

IN these days a book on dynamics rarely describes recent discoveries; it is normally a presentation of long-established facts. It is to be classified according to the class of student for whom it is written, and the clarity and interest of the presentation. The recent work by the late E. H. Smart, entitled "Advanced Dynamics", is for mathematical students (though not wholly for honours mathematicians) and embodies the substance of lectures given to students preparing for London degree examinations. It begins at first principles; but it is not a beginners' book, since even in the first chapters more advanced ideas appear side by side with the elementary ones. The first volume covers such parts of particle dynamics as can be discussed without using generalized co-ordinates. The second deals with rigid dynamics in two and three dimensions, including a full treatment of Lagrange's and Hamilton's equations, but omitting other more advanced analytical topics. Within these limits, the whole forms a full and comprehensive treatise.

It is the book of a teacher. No pains are spared to enable the student to apply dynamical principles. Dozens of examples are worked in the text; and the collections of examples for the student are long and numerous. On the other hand, the discussion of physical principles occasionally leaves something to be desired; subjects of more formal interest—for example, the motion of chains, impulsive motion, and initial accelerations and curvature—are discussed more fully; and the emphasis of the treatment sometimes suggests that the need of getting students through examinations had an undue influence.

The presentation shows the marks of a lecturer; it is bright and interesting, discursive, a little unsystematic, and not infrequently repetitive. It shows that disregard for pure mathematical niceties (especially as regards differentials and limits) which often characterizes lecturers in applied mathematics; it is noteworthy, however, that lax statements are not permitted in proofs on which examination questions can be set. Vector ideas are frequently used, but in an unsystematic manner, the basic results being proved over again for new vectors. I should have preferred to have seen more discussion of the use of complex numbers in oscillatory problems, and of those parts of dynamics used in quantum mechanics. An interesting feature is the historical notes given in the text and at the end of some of the chapters.

The work was produced under difficulties, and the publishers deserve credit for the pertinacity through which it was finally produced. E. H. Smart died in 1945; Mr. F. G. W. Brown undertook the final revision of the manuscript and read most of the proofs; he died in 1949, and his work was finished by a colleague. Partly because of this, the book (especially the first volume) contains a number of slips and misprints, sometimes surprisingly ingenious ones. More unfortunate are a number of actual errors or unsound statements, particularly in Chapters 4 and 9 of the second volume; and an occasional lack of co-ordination between the different sections. Because of these, one would hesitate to recommend the book to a student working by himself; but it is one which teachers of the subject ought to possess.

T. G. Cowling

AN APOSTLE OF HUMUS

The Weed Problem

A New Approach. By F. C. King. Pp. xii+164. (London: Faber and Faber, Ltd., 1951.) 8s. 6d. net.

Mr. F. C. King is the Don Quixote of the self-styled "apostles of humus". He tilts at windmills, with a fervid belief in their aggressive antagonism. He displays the same half-bewildered air of sweet reasonableness alternating with fierce resentment against those who, in his mind alone, dare to seem to disagree with the central article of his faith. His new publication, though ostensibly concerned with the virtues of weeds in gardens, is but a thinly-veiled reiteration of the "muck-and-mystery" creed. It is astonishing that the upholders of this faith seem entirely unable to believe that soil scientists and plant physiologists can see any value in organic material in the soil. To them, the soil scientist is one who advocates the use of inorganic fertilizers alone for the maintenance of soil fertility and, above all, the use of sulphate of ammonia, that *anathema maranatha* of the "composters". One can only charitably conclude that they read solely within their own circle and are unable, therefore, to appreciate that the soil scientist attributes just as great importance to humus-forming materials as they do themselves but for different and more logical reasons. They persist in the view that inorganic fertilizers and organic manures are opposite and alternative instead of being, as the scientist appreciates, complementary.

Although they cannot themselves see it, the whole matter has become for them a cult, an esoteric mystery, in which Nature occupies the theistic role. Their favourite phrase, used repeatedly in Mr. King's book, is "the immutable laws of Nature", and the greatest crime is to transgress these laws, which appear to have been revealed to them alone.

Mr. King's theme in the present book is that we must "preserve the earth's green carpet in accordance with the immutable law of Nature which demands a covering for all fertile land", and this is to be achieved by "controlled weed growth" within the crops. There is much vague and loose discussion of "symbiosis" between weeds and crop plants which abundantly confirms the conclusion that the author has rarely read and certainly not understood scientific publications. Perhaps most astonishing of all is the author's method of explaining away facts contrary to his views by unjustified assumptions from untested premises.

The author gives no really clear-cut practical directions for the application of his ideas on weed control combined with no-digging, but patient seeking through the book brings one to the conclusion that basically his notion is little more than the principle of green manuring with surface-cultivation such as is achieved by rotary tillage, though this latter method is never specifically mentioned. He has obviously thought deeply and observed closely, but lacks the background of knowledge correctly to interpret his observations.

R. H. Stoughton

TECHNOLOGY OF DEFECTS IN PAINTS

Paint Film Defects

Their Causes and Cure. By Manfred Hess. Pp. xvii+544+65 plates. (London: Chapman and Hall, Ltd., 1951.) 50s. net.

This book is the first English edition of the original German book published in 1938; but the present volume has been brought well up to date. Its very title will arouse interest among those who are concerned with the many diverse problems associated with paint deterioration, for, as the author says, "it is the first extensive collection of paint failures ever made". On first consulting this book in a general way one is at once impressed not only by the large amount of effort and time expended in the collection of the necessary material, but also by the thought given to the classification of the experimental results. When, however, one settles down to study a selected topic—following the instructions thoughtfully provided by the author for finding one's way through the labyrinth of possibilities—one realizes that while each topic is discussed exhaustively in all its aspects, the book is essentially practical and not scientific in its approach. It is for this reason that one feels that a word of caution must be given to those readers not versed in scientific methodology. The author has not been discriminating in his selection of the experimental evidence; a host of really useful information based on sound scientific evidence tends sometimes to become smothered by statements of a more superficial character, sometimes contradictory and often open to query. Apart from this criticism, the book is an excellent one; the author is to be congratulated upon its production, as it fills an important gap in the bibliography dealing with paint and allied subjects.

The subject-matter is considered under four main headings, divided into sections, dealing respectively with faults which may develop during storage, during application, shortly after application, and on finished objects when in use. There is also a useful postscript giving an alphabetical list of terms and definitions connected with paint failures. The bibliography is good and the indexing and cross-references—on which the practical value of the book ultimately depends—are extremely thorough. Errors arising from translation are very few, and the book is also remarkably free from misprints. It is a work which cannot be read conveniently section by section, since there is no continuity. It is essentially a reference book, and as such can be strongly recommended as a convenient *vade mecum* for a wide circle of paint technologists.

A. E. A. Werner

Thorpe's Dictionary of Applied Chemistry

Fourth edition, revised and enlarged. Vol. 10: Plagioclase—Sodium. Pp. xi+913. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1950.) 100*s*. net.

WITH the advent of the letter "S" in the tenth volume of the new edition of "Thorpe's Dictionary of Applied Chemistry", the editorial board is within sight of the end of its vast undertaking. One further volume ("SO to Z") and a general index will complete the work. The Dictionary does more than give the latest information on plagioclase, sodium and the rest: it epitomizes the present vitally intimate relation between the science of chemistry and its application in technology. The articles have been contributed almost equally from universities and from the chemical and allied industries. They emphasize that advances in chemical technology are now dependent on and inseparable from advances in chemical science, and will only be made by trained scientific workers. This is a lesson of paramount importance to-day when higher technological education is so much under discussion. There is no short cut to the best technology: it can only grow out of the best science.

The level of the articles has been kept remarkably high. Indeed, I cannot remember a volume of 'Thorpe' so full of informative and interesting material. The editors have made an admirable choice of contributors; to choose at random: Wilson Baker on plant pigments; Bate-Smith on preservation of meat by drying; Brock on pyrotechny; Kellaway on snake venoms; A. R. Powell on platinum; Simonsen on pulegone and other terpene subjects, and so on. Symbolically, there are two excellent articles on rubber—one from a strong British team on natural rubber, and one from an equally strong American partnership on synthetic rubber. Another admirable article is that on quinones by a team from the Dyestuffs Division of Imperial Chemical Industries, Ltd.

To sum up, this is an altogether excellent production giving a vast amount of up-to-date information in a clear and understandable form, and at a reasonable price. A small point may be mentioned: Could something be done to make more obvious the authorship of the individual articles? True, the reader has the necessary clues to enable him to solve the mystery; but is there any need for a mystery?

R. P. LINSTEAD

Annual Review of Physical Chemistry

G. K. Rollefson (editor), R. E. Powell (associate editor). Vol. 1. Pp. viii+382. (Stanford, Calif.: Annual Reviews, Inc., 1950.) 6 dollars.

THIS "Annual Review of Physical Chemistry" makes its début in a volume of eighteen chapters covering a considerable area of the domain of physical chemistry. The majority of the articles are restricted to developments occurring in the period 1948–49 (for example, radiation chemistry, spectroscopy, X-ray structural crystallography, chemical kinetics, photochemistry), but others review more than the past decade (for example, thermochemistry, radioactivity and nuclear theory, theories of valence, experimental molecular structure, statistical mechanics of the crystalline and liquid states).

The articles reflect the modern tendency of physical chemists towards specialization in a particular branch of the subject, for few readers will be able to assimilate the full content of this book in detail. Yet the careful reader will find that the ideas and techniques of one field of specialization often overlap with and have application in another, so that, paradoxically, he advances his own specialization by a knowledge of some other.

Excluding the section on thermochemistry—which is not a review but a remarkable and invaluable bibliography of 825 references—the individual articles achieve a careful delimitation on their choice of material. In consequence, overcrowding is avoided, and criticism and emphasis have not been sacrificed—as witness, for example, the articles by Crawford and Mann on spectroscopy, Beach on molecular structure, Daniels on chemical kinetics, and Longuet-Higgins and Wheland on theories of valence.

This new series of "Annual Reviews" has made a promising beginning, and physical chemists generally will find it useful and stimulating.

H. A. SKINNER

Geschichte der Chemie in kurzgefasster Darstellung

Von Prof. Dr. Georg Lockemann. Band 1: Vom Altertum bis zur Entdeckung des Sauerstoffs. (Sammlung Göschen, Band 264.) Pp. 142+4 plates. (Berlin: Walter de Gruyter und Co., 1950.) 2.40 D. marks.

THIS small book gives a very interesting and competent survey of the history of chemistry from the earliest times to the discovery of oxygen. The author is known for his articles on the subject in German chemical journals and has an excellent knowledge of recent publications on the history of chemistry. His text is therefore based on recent investigations. The amount of information given is quite surprising when the size of the book is considered, and there are eight portraits on art paper at the end. The bibliography contains exclusively German books, and there is not space for detailed references. Some names are given incorrectly, and as these errors are distributed impartially among nationalities, including German, it must be assumed that they are due to careless proof-reading and may be corrected in later printings of this very useful little work.

J. R. P.

Electronics

By P. Parker. Pp. viii+1050. (London: Edward Arnold and Co., 1950.) 50*s*. net.

THE scope of a course on electronics has undergone a gradual change during the past fifteen years. Before the War what was required was, in general, an introduction to radio communications engineering. In a text-book on this subject one expected to find a brief introduction on electron tubes or radio valves, followed by a discussion on power supplies, amplifiers and oscillators. Propagation of electromagnetic waves and aerial systems would be dealt with fully, and finally a few typical circuits of receivers and transmitters would be examined.

The present volume makes, and needs, no apologies for the fact that the words electromagnetic waves, automatic volume control and telegraphy do not appear in its index. It is intended as an introduction to the physics of electron tubes, and circuits are dealt with only so far as they illustrate the properties of the tube. Vacuum and gas-filled tubes of great diversity are dealt with, including cavity magnetrons, on one hand, and Geiger counters, on the other. Throughout the book there is an emphasis on the physics of the devices considered: thus there is a good introduction to electron optics.

The book is stated to require no more than an advanced school knowledge of physics, and this accounts for explanatory notes on, for example, the Bohr atom and kinetic theory. There are good bibliographies with suggestions for further reading at the end of every chapter, and exercises with answers to numerical problems are provided.

U. W. ARNDT

Electricity and Magnetism

Classical and Modern. By Dr. G. B. Deodhar and K. S. Singwi. Pp. viii+507. (Allahabad and Benares: Students' Friends, 1949.) 15 rupees.

THE authors, who are members of the staff of the Physics Department of the University of Allahabad, have covered the main topics in the subjects of electricity and magnetism at a level which is adequate for a pass degree in physics. Some of the material included, such as Maxwell's electromagnetic equations, goes beyond the usual range of a pass degree course, but generally the treatment is neither sufficiently advanced nor sufficiently comprehensive to meet the full needs of an honours course in physics.

The book is divided into two sections, classical and modern. The classical section covers the usual field, particular prominence being given to measuring instruments and their uses. The modern section outlines the subjects of the conduction of electricity through gases, electronics, positive ray analysis and isotopes, atomic structure, X-rays, photoelectricity, natural radioactivity, artificial transmutation of elements, electron waves, cosmic rays, terrestrial magnetism and atmospheric electricity.

The book is lucidly written and well illustrated, and because emphasis is laid on experiments and physical concepts it should appeal to students with limited mathematical attainments. The quality of the printing and the trimming of the pages leave much to be desired.

A. H.

Die elektromagnetische Schirmung in der Fernmelde- und Hochfrequenztechnik

Von Dr. Heinrich Kaden. (Technische Physik in Einzeldarstellungen, herausgegeben von W. Meissner, Band 10.) Pp. viii+274. (Berlin, Göttingen und Heidelberg: Springer-Verlag; München: J. F. Bergmann, 1950.) 38 D. marks.

AS is justly remarked in the preface, no collected and systematic presentation of the principles of electromagnetic screening has hitherto been available. The author, with his long experience in these problems at Siemens–Halske, has been successful in filling the gap with this present book. Though the approach is essentially theoretical, it is concise and thorough and contains material, much of which is new, and most of which will prove valuable to the communications engineer who is concerned with screening at audio and radio frequencies.

The first part, "Screening against Disturbing Fields", which lays somewhat more emphasis on magnetic than on electric screening, deals with both closed and open screens and with the effect of slits, holes and gaps. Screening by grids and meshes of wires is only rather briefly treated. The second part, "Screening against Disturbing Currents", is concerned with undesired pick-up on the inner conductors of a cable due to imperfections of conductivity or continuity in the outer screen and with cross-talk between cables.

There is a short appendix which summarizes the properties of Bessel and Legendre functions and gives a selected bibliography of forty-nine references. A moderate level of mathematical knowledge in the reader is assumed, but the author has been careful to introduce and develop the techniques in a manner which is readily applied to similar problems having different boundary conditions.

R. E. BURGESS

L'Analysis situs et la géométrie algébrique

Par S. Lefschetz. (Collection de monographies sur la théorie des fonctions.) Pp. vi+154. (Paris: Libr. Gauthier-Villars, 1950.) 650 francs.

THIS reprint restores to currency one of the most famous of the Borel tracts. The study of algebraic functions of a single variable rested securely on the pillars of function theory and topology, but the extensions and generalizations to higher dimensions were unsatisfactory until Lefschetz took the whole matter in hand; his investigations up to 1924 are summed up in this volume—not altogether easy reading and in places displaying some of the roughness of pioneering work, but full of ideas and brilliantly stimulating. The central position of topological notions in the field of algebraic geometry is clearly brought out in studying algebraic surfaces, systems of curves on algebraic surfaces, algebraic varieties, and the related Abelian integrals. From this guiding clue much of the very considerable progress made during the past twenty-five years in the domain of algebraic geometry has arisen. An account of this progress is to be found in Prof. W. V. D. Hodge's presidential address to the London Mathematical Society in 1949 (*J. Lond. Math. Soc.*, 25, Part 3; July 1950), in which the great debt owed to Lefschetz by all algebraic geometers is fully acknowledged. The impact of Lefschetz's contributions on the topic is so weighty that his tract, even in unrevised form, is still an indispensable text for the serious student of the subject.

Functional Operators

By John von Neumann. Vol. 1: Measures and Integrals. (Annals of Mathematics Studies, No. 21.) Pp. vii+261. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1950.) 22*s*. 6*d*. net.

THE general mathematical theory of operators has been much advanced by von Neumann's lectures at the Institute for Advanced Study, Princeton, now printed in the "Annals of Mathematics Studies". The first volume is almost entirely devoted to the theory of integration, which is given in a completeness probably beyond what will be required in the second and succeeding volumes.

About one-third of the book deals with the theory of Lebesgue measure and integration, in n-dimensional spaces, giving a concise and fairly comprehensive account of the basic concepts and theorems on the Lebesgue integral. The rest of the book is divided about equally between two chapters, one of which generalizes the measure theory to abstract spaces, and incidentally provides a definition of the Lebesgue integral independent of the topological ideas usually involved; the last chapter gives a thorough discussion of the general integral, and deals in detail with the derivative of one set function with respect to another.

The whole treatment is detailed, accurate and painstakingly thorough. It will, of course, appeal only to the pure mathematician with a taste for abstract spaces, but to such a reader the exposition will present no great difficulty.

ARCTIC AEROBIOLOGY

POLLEN GRAINS AND OTHER SPORES OBSERVED ON STICKY SLIDES EXPOSED IN 1947

By PROF. NICHOLAS POLUNIN
McGill University, Montreal*

PREVIOUS communications on this subject have been mainly concerned with preliminary explanations and observations[1] and with the fungi and bacteria[2] which colleagues were able to isolate from colonies developing on nutrient plates that I exposed when flying northwards to the Arctic Ocean and the vicinity of the North Magnetic Pole in 1947. Already in the first paper it was explained how, in conjunction with each such exposure, a 'Vaselined' microscope slide was so held in a specially constructed wood and metal holder that ". . . the sticky surface was exposed against the air-stream for five minutes in about the same position outside the aircraft as the nutrient plate", and a subsequent communication[3] mentioned that, ". . . on some of the slides exposed near the Arctic Ocean coast there are represented spores of three of the most important airborne pathogens of cereal crops of Canada, namely, wheat stem-rust (*Puccinia graminis tritici*), wheat leaf-rust (*P. rubigo-vera = P. triticina*), and foot-rot of barley and rye (*Helminthosporium sativum*)".

It is the object of the present paper to give numerical and other details of the findings, by direct microscopic observation, of pollen grains, pteridophytic and bryophytic spores, and the spores of pathogenic or other fungi, that proved to be present on these slides which I exposed on the four air sorties described in the next paragraph, and which were early sent for examination to Dr. B. Peturson, Dominion Laboratory of Plant Pathology, Fort Garry, Manitoba, and to Dr. N. W. Radforth, of McMaster University, Hamilton, Ontario. To these two workers, and their assistants, my warm thanks are due—as also to Dr. Roger P. Wodehouse, of the Lederle Laboratories, Pearl River, N.Y., for further help and his expert guidance particularly in the matter of pollen grains. I would also like to take this opportunity of acknowledging indebtedness to the Royal Canadian Air Force for the splendid facilities afforded, and of expressing personal admiration for my two friends and principal pilots, Flight-Lieutenant J. F. Drake and Squadron-Leader William Carr.

The four sorties on which the exposures were made in 1947 were as follows: (1) on August 12 in a single-engined 'Norseman' aircraft from an unnamed lake (which I called Canso Lake, lying north-west of Great Bear Lake) in a northerly direction to Langton Bay on the Arctic Ocean coast, and thence in a north-westerly direction to the mouth of the Horton River near Cape Bathurst, the most northerly point of the western Canadian mainland; (2) on August 26 in a twin-engined 'Canso' flying-boat from Cambridge Bay, Victoria Island, in a north-easterly direction to the southernmost extremity of Somerset Island, then northwards until bad weather intervened in about latitude 73° N.; (3) on August 27 in the same flying-boat from Cambridge Bay in a south-south-westerly direction to Yellowknife, Northwest Territories; (4) on September 5 in the same flying-boat almost due south to Edmonton, Alberta. These routes were indicated on a sketch-map in the first communication[1], and the approximate positions of exposure were spotted in the second paper[2], which also indicated the approximate times of exposure, airspeeds, geographical co-ordinates, and altitudes. The positions of exposure are more accurately indicated in the accompanying sketch-map (Fig. 1), on which the Roman numerals refer to the individual sorties. With the altitude generally around one mile and the airspeed some 100 knots (115 m.p.h.), an attempt was made to expose a fresh slide and plate every twenty air miles during the first two sorties, and every thirty air miles during the third and fourth; but bad weather, icing, and preoccupation with landing and my other duties resulted in some irregularity and particularly lengthy gaps at the beginnings of flights 3 and 4. Apart from these gaps, it was possible to obtain an almost unbroken transect in the form of these periodical exposures extending over some 1,500 miles from the vicinity of the North Magnetic Pole to Edmonton, Alberta—besides the 'preliminary' northwards to the Arctic Ocean coast farther west.

The results as well as other pertinent data are indicated in the accompanying table, which scarcely requires explanation except as regards the unfortunately high proportion of uncertainties among the pollen grains and bryophytic spores, particularly; they are due to discrepancies between the observa-

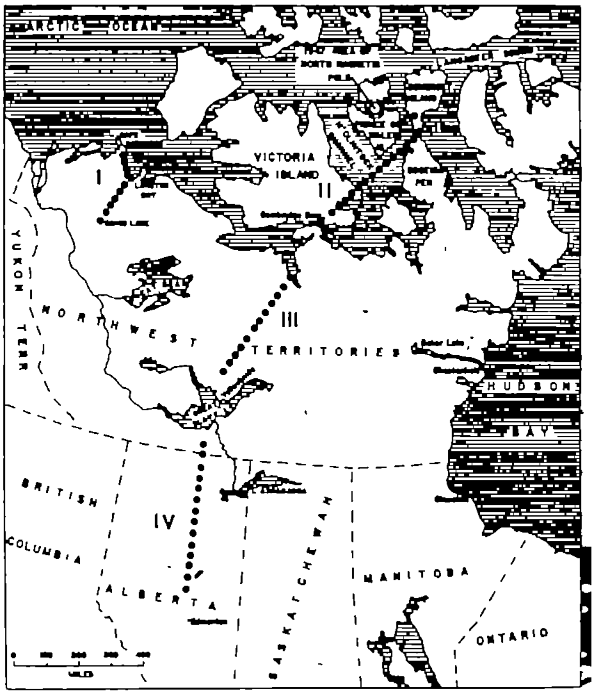

Fig. 1. Exposure of plates over north-west Canada in 1947. Roman numerals refer to individual flights

---

* Now on leave of absence with a Guggenheim Fellowship and Honorary Research Fellowship at Harvard University, Cambridge, Mass. This paper was prepared during the winter of 1949–50; but the results here published were not fully cleared until more than a year later. In the meantime an account of part of the same material has been published independently in *Phytopathology* (40, 682; 1950). (Footnote added in proof.)

tions of different specialists who were either looking for other things or trying valiantly to observe without staining (for fear that treatments planned for the future might be precluded by such an operation). It is also possible that some of the grains had been accidentally removed in the meantime, for the slides were loose in their individual, though well-wrapped, containers. In all, fifty-two slides were exposed (No. 12 was omitted) and their full re-examination in this connexion was not attempted—more because it would have been of doubtful validity in view of all that the slides had by then been through than because of the considerable labour involved.

Although the results given in the table seem practically to speak for themselves, a few items are considered worthy of comment; nevertheless, it should be emphasized that it would be dangerous to generalize except perhaps in the most tentative manner from such limited experiences and relatively few observations as these 'preliminary studies' afford.

(1) These observations evidently confirm the presence of pollen grains and the spores of Pteridophyta and pathogenic fungi in the air above remote treeless and even ice-bound regions northwards at least beyond the seventieth parallel of north latitude —cf. Meier and Lindbergh[4], whose "Fig. 12. Types of objects trapped above the Arctic Circle on slide 15" ("exposed on August 6 for forty minutes at an average altitude of 3,000 feet above sea level over the coast of Greenland between Scoresby Sound and Clavering Island, north of 70 degrees latitude" in 1933) appears to include items representative of each of these three categories. Unfortunately these authors' promised detailed results were never published, owing to Meier's untimely death, and I have been unable to

locate any of their material—at least, in a suitable state for working out.

(2) On the earliest flight, the northernmost catch of a winged pollen grain of a coniferous plant was made in latitude 69° 28′ N., which is well north of the nearest likely source (cf. the recent report by Dyakowska[3] of their persistence in the air near sea-level off the west coast of Greenland at least as far north as the vicinity of Godthaab (lat. 64° 11′ N.), although in this case, in spite of the lower latitude, the nearest likely source was much more distant).

(3) Spores of various all-too-familiar pathogenic fungi were found far north of their probable nearest point of origin—in the case of uredospores of wheat stem-rust to 70° 02′ N. at a point which, as already reported[3], "... is the better part of 1000 miles north of the Peace River region, which is the nearest likely source of supply of any real extent, and would seem to extend remarkably the much-cited 'at least 200 miles' that spores of [this] important parasite (which alone has caused an estimated loss in western Canada through injury to the Wheat crop of as much as $200,000,000 in a single year) are known to have been disseminated". Although with these small numbers the possibility of error due to contamination is by no means ruled out, the general conditions and controls and other observations suggest that it is slight and indicate the probable validity of these results. So supposedly there is frequent danger of infection as a result of such long-distance dispersal, though it may be noted that the positive and plentiful smut spore observations were practically limited to the two air-masses of supposedly southern Canadian origin—see (6). Indeed, the only exception identified is expressly noted by Dr. Peturson as "not a cereal Smut . . . possibly a grass Smut" (a considerable range of Ustilaginales parasitize Cyperaceæ, Polygonaceæ, etc., very plentifully and widely in the Canadian Arctic as noted by Linder[4]).

(4) Although spores of *Helminthosporium sativum* and *Alternaria* spp. (not necessarily pathogenic) were very widespread, they appeared to be relatively sparse; the only counts at all high of spores identified on these slides were obtained on the southernmost flight and involved chiefly stem and leaf rusts and smuts, which alone assumed numbers suggestive of epidemic conditions (cf. the mimeographed Twenty-seventh Annual Report of the Canadian Plant Disease Survey, 1947). It is also mainly in the southernmost forested regions that other bodies, including the spores of Pteridophyta and Bryophyta, appear to have become relatively plentiful—possibly suggesting loss by gravitational sedimentation or removal by precipitation to the north, although the high counts of rusts and smuts from not so far south of Yellowknife as to be still well north of the belt of widespread cultivation would seem to indicate that such loss is not necessarily rapid. One is apt to get a picture of sweeping gusts and upward air-eddies in the sun-heated, cultivated plains of the south carrying disseminules to high altitudes—at which they may travel northwards on strong winds until they meet a cold front, for example, when precipitation contingent on this meeting may remove them from the air, or, if it does not, turbulence will be likely to confuse the issue. Farther north, in the real Arctic, the precipitation tends to be very slight and the winds almost perpetual, so that any particles which lie aloft in the atmosphere may be expected to stay up for a long time. What proportion remains viable under the radiation and other conditions obtaining, and for how long, might be worth investigating, though at present it seems likely that ultra-violet radiation may be less harmful to micro-organisms in the Far North than to the south.

(5) Actually, the probable explanation of the high counts on the first three slides exposed after leaving Yellowknife is that I was then flying in a different air-mass from that encountered thereafter—with such surprising rapidity that I noticed the marked temperature rise on my hand as I put it out to make the fourth exposure. Warm air persisted throughout the remainder of the flight to Edmonton, and according to the trajectory analyses kindly furnished by Mr. K. T. McLeod, of the Air Services Meteorological Division, Department of Transport, Canada, was of south Alaskan origin in its northern part and almost due westerly in its southern part. But only this southern part of the warm air of westerly origin had come over much southern, cultivated land; and it was this southern part which gave most of the high counts. The other high counts were afforded by the first three slides exposed on this last flight, and it is remarkable that the trajectory of this air-mass, although it was travelling eastwards just then, indicated that it had so swept around that eighteen hours previously it was travelling westwards some two hundred miles to the north and, a few hours before that, had been much farther to the south-east—with some indication of having previously come over the cultivated prairie regions like much of the air encountered near Edmonton. The air-mass trajectories for this fourth flight are indicated in Fig. 2. The correlation in this case is extraordinarily close, and is supported by the spores of the higher plants as well as those of fungi; thus whereas on the first three slides exposed after leaving Yellowknife (Nos. 40–42, while I was in air of probably southern origin) there were found no less than 349 identifiable spores, etc., on the next three (Nos. 43–45, exposed in Alaskan air) there were identified but seven, and six of these were on the sixth slide (No. 45),

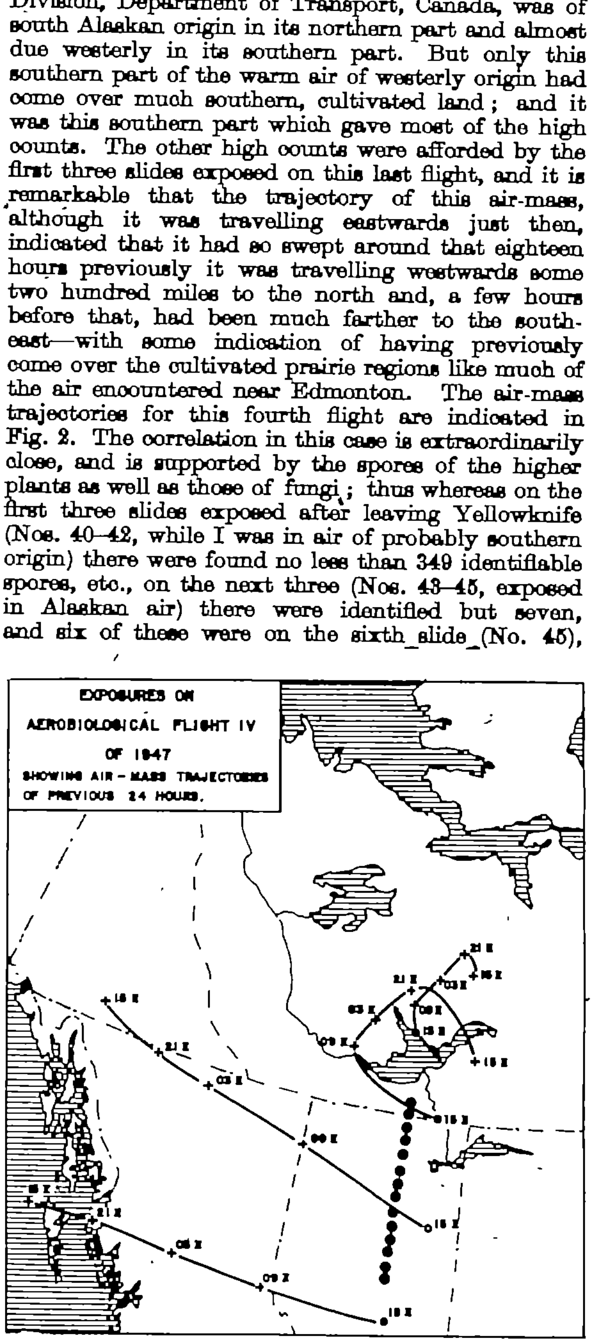

Fig. 2

after which numbers rose rapidly—presumably as the southern air from the west was encountered. Such a clear and potentially valuable correspondence between air-masses and their spore, etc., load is largely to be expected when we think in terms of regions of origin, and perhaps is not necessarily much confused by mixing or loss by sedimentation, etc., even during long and tortuous travels.

(6) Analysis of the paths of the air-masses in which the other flights were made seems less significant, and in any case Mr. McLeod warned that in these instances the lack of upper-wind data made their earlier movements doubtful. However, it seems that the second sortie was in northerly winds coming from arctic Canada, and probably of just that origin—which may well explain the lack of uredospores and gymnospermous pollen and the general paucity of material caught. The third sortie, however, is interesting in its seeming support of the implication of the previous paragraph that the load of particles, etc., carried by an air-mass depends more on its origin, or at least its history, than on its trajectory or actual position at any time: for whereas the early stages of this flight were made in air-masses coming from the north, as was the case in the second flight, and the results were similarly so nearly negative that the slides constituted a kind of control, the last stage coming in towards Yellowknife was in air of north-westerly origin, which appeared to have a trajectory not unlike that of the air-mass in which the first flight of all was made, and actually showed a more comparable spore load.

(7) It appears that although the smaller spores of crop pathogens are alone apt to be at all numerous, pollen grains and other spores of a wide variety of types and, especially of anemophilous species carry quite well in the atmosphere, and certainly some can occur at high altitudes[7] and in remote regions not merely over land but also over the ocean[8]. All too little is yet known of the extent to which they may remain viable; but it has been determined that a range of pollens of by no means hardy types can give a high percentage of germination and produce strong seedlings even after the greater part of a year of storage[9], and that low temperatures and light-ntensities and atmospheric pressure (but medium humidities) can favour pollen longevity[9,10]. In these and other circumstances, such as the almost perpetual windiness preventing particles from settling, it seems conceivable that the possibilities of long-range and hence 'absent-treatment' hybridization even among plants which do not practise the 'spring-flowering idea' may be greater in the Arctic than in some climatically more favourable regions where dense foliage, etc., impedes take-up and effective falling of 'pollen rain'—as well as where much of the atmospheric pollen is removed by precipitation—and may perhaps be one of the factors behind the tiresome 'plasticity' of many groups of arctic plants, including, particularly, the Gramineæ, Cyperaceæ, Juncaceæ, Salicaceæ, Cruciferæ, Rosaceæ, and Compositæ.

In conclusion, it should be re-emphasized that these suggestions are largely tentative, being based on too limited experience and too few data to allow sound generalization. It may even be objected that the small numbers of significant items observed on many of the slides are not beyond the possibilities of contamination; but the precautions taken, the advice of examining specialists, the working of controls, and the over-all picture now that it is possible to see it, all give confidence that even individual observations have value and probable validity. The above data are published with the approval of the Defense Research Board of Canada, which has generously supported the continuation of this work with an extra-mural grant in my name.

THE JOULE MUSEUM, SALFORD

THE Joule Museum, which was opened on July 3 at Joule House, Salford, contains a permanent exhibition of apparatus and documents and is intended to be a comprehensive presentation, by original or replica, of J. P. Joule's major scientific work. The existence of this exhibition is due to the initiative of the British Society for the History of Science, which delegated the task of forming the Museum to Prof. L. Rosenfeld, University of Manchester; in this, Mr. J. A. Newth was a ubiquitous lieutenant.

The nucleus of the Museum is a collection of original apparatus and documents which had been acquired by the Manchester College of Technology—through the agency of Prof. W. W. Haldane Gee—after Joule's death, when his house and property at Sale were disposed of. They have since been preserved at the College of Technology, where they could not be properly exhibited for lack of space. This collection has now been completed by replicas from original apparatus preserved elsewhere, and the whole has been displayed in a room of a house at Salford in which Joule lived for some years, and which is now owned by Salford Corporation. A grant of money from the University of Manchester and the provision of this room in Joule House, arranged by Mr. A. J. Rivett, director of education for Salford, made it possible to display the collection to the best advantage.

The replicas of apparatus have been constructed by Mr. R. Bradford in the workshop of the Physics Department of the University of Manchester. Apparatus was lent for this purpose by the Science Museum, South Kensington, London, through the agency of Mr. J. Chaldecott, and by the Department of Natural Philosophy, University of Glasgow, with the co-operation of Prof. P. I. Dee. The documents comprise a large laboratory book, some notebooks, manuscripts and letters, which come from a variety of sources.

The exhibits are arranged in sections which follow each other chronologically. The early experiments sprang out of a desire to improve Sturgeon's electromagnetic engine, and to arrive at a quantitative estimate of its "duty" or efficiency. There are shown a number of toy-like models of electrical motors and cores of electromagnets of various constructions which were used to study their "lifting-power". This section recalls Joule's friendship for William Sturgeon, whose encouragement may have determined the direction of these early experiments.

In the next period (1840–43) was performed a series of experiments concerned with the connexion between electricity and heat. A reconstruction of the simple apparatus which Joule used to measure the heat produced in a conductor by an electrical current is shown, together with a replica of the remarkable arrangement by which he confirmed his allegiance to the theory that heat is a mode of motion, and first established the equivalence between work and heat. A coil is mounted inside a cylindrical calorimeter (25 cm. × 10 cm.) and can be rotated between the poles of a fixed electromagnet. Joule was able to show that heat is actually generated in the coil by the induced current and that this heat is proportional to the mechanical work done in turning the apparatus. Direct voltaic currents were superimposed on those induced in the coil, and the measurements of the heat produced led to the conclusion that, in these experiments, mechanical work was converted into heat through the intermediary of electricity.

In 1844 Joule turned to a study of the heat changes accompanying the expansion and compression of gases; the original apparatus used in this series of experiments is exhibited in a complete state. Two large cylindrical copper vessels were connected through a needle valve ("the invention of Mr. Ash, of this town"). One of the cylinders was evacuated; the other could be filled to a pressure of 22 atmospheres by 300 strokes of a hand-pump. By immersing the whole arrangement in a calorimeter and opening the valve, Joule discovered that "no change of temperature occurs when air is allowed to expand in such a way as not to develop mechanical power". Unknown to him, this law had already been found in 1806 by Gay-Lussac; it played an essential part in the reasoning by which Robert Mayer deduced in his own way the mechanical equivalent of heat in 1842.

The next period (1845–49) was occupied with the famous friction experiments. Replicas are shown of the two paddle-wheel calorimeters, for the friction of water and mercury, and of that which contained two metal plates in close contact and which was used to produce heat by the friction between solids. All these systems were activated by falling weights. Unhappily, the thermometers which were used in Joule's experiments and preserved by the Manchester Literary and Philosophical Society were destroyed in an air-raid; there remain but a few relevant documents, including the invoice from the French firm which supplied some of them.

One of the most important events of Joule's life was his meeting with William Thomson (later Lord Kelvin) at the British Association meeting of 1847. This was the beginning of a long period of fruitful co-operation and mutual stimulus. For Thomson, it was the starting-point of the investigations which led him, shortly after Clausius, to the recognition of the two fundamental laws of thermodynamics.

In exploring the consequences of these laws, Thomson pointed out that a gas would be cooled by allowing it to expand into a region of lower pressure, and in 1852 Joule and Thomson started a long series of experiments which confirmed this deduction. There are exhibited the wooden containers for the porous plugs which were used to separate the regions at high and low pressure, and the few other surviving parts of the apparatus.

Joule's last experimental work, in 1878, was a new accurate determination, by the paddle-wheel friction method, of the mechanical equivalent of heat. It was undertaken at the request of the British Association Committee on Standards of Electrical Resistance, in order to clear up a discrepancy between the previous friction value and that derived from the heating effect of a current passing through a resistance which had been compared with the standard issued by the Committee. A replica of the calorimeter used by Joule for this experiment is exhibited, together with Joule's British Association standard resistance. The resulting value for the equivalent was almost identical with that obtained thirty years before by the same method.

The last section of the exhibition is devoted partly to some instruments which were probably permanent features of Joule's laboratory, and partly to a selection from a number of odd pieces of apparatus used in minor investigations of a varied character—especially in a careful study of the mechanism of steam condensation. Joule's precision instruments were made by John B. Dancer, an optician and scientific instrument maker of great reputation who carried on business in Cross Street, Manchester, from 1841, and was himself a distinguished amateur of science.

Documents and letters of special interest are displayed at appropriate places in the various sections, and also in separate show-cases. On the walls hang a portrait of William Sturgeon and two portraits of Joule himself. One of them is a photograph of the portrait by Collier owned by the Royal Society, and exhibited by permission of the Council of the Society. The other is a large oil-painting on loan from the Manchester Literary and Philosophical Society, which replaces the original portrait by Patten destroyed in the air-raid of 1940.

While the scientific aspect of Joule's investigations can be reconstructed in a fairly complete way, it is a matter of regret that so few documents have been preserved which could throw light on his personality. Why did he devote himself to scientific pursuits when so much else might have been expected of a rich brewer's son? Who taught him the rudiments of his craft, and inspired his father to build him a laboratory? Whence came that almost arrogant courage which relied on the visual subdivision of a thermometer interval into twenty parts for the enunciation of a new law of Nature? What gave him such an ascetic devotion to a principle when his city was crying out for technical improvements and inventions?

It would be interesting to know more of his relations with people like Dalton and William Sturgeon, of his wife and family. There is some evidence that he was handicapped by a physical deformity that may have made him a recluse. It is certainly true that the last years of his life were given up to the infirmity of old age. But it is strange that so much can have been forgotten about a man whose life-span overlapped that of our fathers.

The Joule Museum is open to the public, on application to the offices of the Child Guidance Clinic on the ground floor of Joule House, 49 The Crescent, Salford; parties or individual visitors who would like to be accompanied by a member of the staff of the Physics Department of the University of Manchester should make arrangements in advance with Prof. L. Rosenfeld at the Department.

THE CHEMICAL RESEARCH LABORATORY, TEDDINGTON

THIS year 'open days' at the Chemical Research Laboratory, Teddington, were held during September 19–21, and many representatives of industrial firms, universities, government departments and the Press took the opportunity to view the work in progress. It may be mentioned that a new laboratory is under construction, although it was not open to inspection this year; this is designed for chemical work with radioactive materials and will be ready for occupation during 1952. In addition, plans for a new microbiological laboratory have been drawn up and construction will begin this year. A useful addition to the facilities of the Laboratory is a new glass-working hut, equipped with lathe and other apparatus for high-grade work. Researches were illustrated by many exhibits, and this article is confined to some indication of the general programme of the six research units, and a more detailed description of some of the newer exhibits.

The Corrosion of Metals Group is concerned with corrosion and its prevention in immersed, atmospheric and underground conditions. This includes work on the development of accelerated corrosion tests, the application of inhibitive methods, and new work on boiler-tube corrosion. The Group has a special interest in the surface films on metals, and the chief object of new work on the oxidation of metals below 250° C. is to provide experimental data that may be used to test or formulate theories on the oxidation of metals in this temperature range. In these experiments particular attention has to be paid to the physical and chemical nature of the metal surface employed. The properties of the electrolytically polished surfaces of polycrystalline copper sheet of high purity have been examined by the optical microscope, by electron diffraction and by an electrometric method. The last-named enables the very thin oxide films (~ 25 A.), formed during surface preparation, to be measured and provides a ready means of detecting the presence of certain undesirable contaminating layers on the surface, if they are present. Kinetic studies on the oxidation of these samples at pressures in the range 10^{-1}–10^{-4} mm. of mercury, using a manometric technique, have revealed that the oxidation-rate is markedly dependent on the oxygen pressure. This variation is of considerable theoretical interest, and a full-scale investigation using a micro-gravimetric procedure is now in progress.

Interesting work on the electrode-potential behaviour of metal specimens in anaerobic culture media inoculated with *Desulphovibrio desulphuricans* has been commenced. In particular, the polarization characteristics of the metals in conditions suitable for the vigorous proliferation of sulphate-reducing bacteria are being studied.

The Radiochemical Group is mainly engaged on a programme of work for the Ministry of Supply on the analysis of radioactive minerals and ores, and the concentration of metals from low-grade sources. A recent advance is the application of ion-exchange resins in separation processes. If a solution containing a mixture of metals is passed through a column of cation-exchange resin, the metals are absorbed in amounts depending on their concentration in the solution and their affinity for the particular resin used. Not only can a dilute solution be concentrated and freed from unwanted anions, but also, by choosing the correct conditions, the process can be selective for a particular metal. An exhibit demonstrated how a multi-column adsorption system can be employed for this purpose. Work on the separation of metals by paper-strip chromatography or cellulose columns has been continued, and a new separation exhibit was that of platinum and palladium from iridium.

The Inorganic Group has been working on a variety of topics, such as the extraction of gallium and germanium from flue dust, and the conversion of rock phosphate into fertilizer by methods designed to reduce the consumption of sulphuric acid. The Group is also responsible for the microanalytical and spectrographic analytical work required by the Laboratory.

Germanium continues to find an increasing use for micro-wave rectification and as a substitute for the triode valve. Considerable difficulty has been experienced in producing material of the necessary high degree of purity, one of the most troublesome impurities being arsenic. The problem has been studied using radioactive tracer methods, and a method of purification has been developed which yields germanium dioxide containing less than 0·01 p.p.m. of arsenic, and which is well suited to commercial application. Germanium metal derived from this oxide has a satisfactory electrical performance. The work is being continued with the view of the elimination of other elements, notably boron, which may be present in minute traces and may affect the electrical properties of the metal.

A feature of the work of the Organic Group is the preparation of organic compounds in a high state of purity and the determination of precise physicochemical data in collaboration with the National Physical Laboratory; this includes the lower hydrocarbons used for the calibration of mass spectrometers, cyclic and heterocyclic compounds, and long-chain fatty acids. The Laboratory is now equipped with low-temperature distillation units (including a Podbielniak 'Hyd-Robot') for the preparation of pure low-boiling hydrocarbons, and spinning-band fractionating columns for the distillation of the esters of long-chain acids.

Part of the work in collaboration with the National Physical Laboratory is the determination of the end-products of combustion of nitrogen-containing compounds in the bomb calorimeter. An oxygen-purifying train for the preparation of pure oxygen, and apparatus for analyses of the bomb contents, were on view. Studies of the synthesis of compounds containing labelled carbon have been continued, and some new syntheses, including ring-labelled aromatic compounds, were exhibited. γ-Resorcylic acid has been prepared for clinical tests for the Medical Research Council.

A discovery of great potential importance in connexion with the determination of molecular weights of polymers by osmotic measurements has been made in the High Polymers Section. It has been found that polyvinyl alcohol may be used for preparing improved semi-permeable membranes which possess the advantages of permitting very rapid passage of the common polymer solvents and yet enable rapid and accurate measurements to be made of the number-average molecular weights of polymers of considerably lower degrees of polymerization than heretofore. Furthermore, osmometers of very simple design may be used.

The shortage of sulphur has stimulated inquiry into new sources. The possibility of using micro-organisms for sulphur production from indigenous sulphates is being examined by the Microbiology Section. In June 1950 two members of the Section examined some sulphur-producing lakes near El Agheila in the Cyrenaican desert; they found that the formation of sulphur was due to the combined action of sulphate-reducing and photosynthetic sulphide-oxidizing bacteria. Details of the expedition, illustrated by maps and photographs together with many of the samples actually obtained, were exhibited. Of special interest was a demonstration of the production of sulphur by the symbiotic action of pure cultures of the two types of organisms isolated from the Cyrenaican lakes in a medium containing sulphate as the sole sulphur source.

Included in the Microbiology Section is the National Collection of Industrial Bacteria. Although still in its formative stage, the Collection now maintains more than five hundred strains. Its usefulness is indicated by the increasing world-wide demand for its cultures; last year, more than four hundred strains were supplied to twenty-seven countries. The multifarious activities involved in maintaining cultures were demonstrated, for example, the technique of vacuum freeze-drying; diagnostic bacteriological and biochemical tests used for identification and classification; card index system; package and storage. The use of specific types of bacteria for the assay of antibiotics was illustrated.

NEWS and VIEWS

National Science Foundation, Washington: Dr. Paul E. Klopsteg

Prof. Paul E. Klopsteg, professor of applied science and director of research of the Northwestern Institute of Technology, has been appointed assistant director of the National Science Foundation for the Division of Physical, Mathematical and Engineering Sciences. Dr. Klopsteg, formerly president of the Central Scientific Company, has long been associated with the administration of research. During the Second World War he served with the Office of Scientific Research and Development as chief of Division 17, Physics and Special Devices, of the National Defense Research Committee, which developed important equipment and devices for war-time use. Notable among the Division 17 developments were the three 4,000,000-volt X-ray machines built by the University of Illinois under contract with the Office of Scientific Research and Development, and the high-voltage Van de Graaff machine developed under contract with the Massachusetts Institute of Technology for the X-ray inspection of heavy military equipment. Later in the War, Dr. Klopsteg was appointed assistant chief of the Office of Field Service, which organized the supply of scientific consultants to the various theatres of war; in this capacity he was made chief of the Research Division, General Headquarters, Southwest Pacific Area in Australia and New Guinea in 1944. Dr. Klopsteg was awarded the Medal for Merit with Presidential Citation for his war-time work. Continuing his association with Federal research activities since 1945, he has been a member and chairman of the board of governors of the Argonne National Laboratory, operated by the University of Chicago under contract to the U.S. Atomic Energy Commission. Dr. Klopsteg has been director and treasurer of the American Association of Physics Teachers and chairman of the executive committee of the American Institute of Physics. In his leisure he has studied archery, and he is an honorary member and former chairman of the board of governors of the National Archery Association in the United States.

George Francis FitzGerald Centenary

The Royal Dublin Society will hold a special scientific meeting at 4 p.m. on October 30 to mark the centenary of the birth of George Francis FitzGerald. FitzGerald played a prominent part in many branches of theoretical physics during the last two decades of the nineteenth century, and was the first to show that the generation of electromagnetic waves by oscillating electric circuits was theoretically possible, a prediction verified a few years later by Hertz. He is probably best remembered to-day as one of the authors of the FitzGerald–Lorentz contraction hypothesis, a forerunner of the theory of relativity, which he and Lorentz put forward independently to explain the null result of the Michelson–Morley experiment. The meeting will accordingly be devoted chiefly to the presentation of communications dealing with some modern views on relativity theory. These will include the following papers: Dr. H. E. Ives, "The FitzGerald Contraction"; Prof. W. H. McCrea, "The FitzGerald–Lorentz Contraction—some Paradoxes and their Resolution"; Dr. G. J. Whitrow, "The FitzGerald–Lorentz Contraction Phenomenon and Theories of the Relativity of Galilean Frames"; Prof. J. L. Synge, "Effects of Acceleration in the Michelson–Morley Experiment"; and Prof. F. E. Hackett, "FitzGerald as revealed by his Letters to Heaviside". It is hoped that in addition Dr. E. H. Alton, provost of Trinity College, Dublin, and Prof. H. H. Dixon will contribute personal reminiscences of FitzGerald.

Training of a Technologist

In his Redwood Lecture "The Training of a Technologist", delivered to the Institute of Petroleum on October 3, Prof. F. H. Garner, professor of chemical engineering in the University of Birmingham, emphasized the importance of the applied scientist possessing, besides his technical knowledge, some understanding of the human mind, personal qualities of leadership and the knowledge of how to handle men, which can be gained only by personal contact and not through books. Prof. Garner did not agree that education should be based solely on the humanities, but he pointed out that the defects of such an education, particularly when it includes no training in science nor any scientific background, is due at least in part to the decay of the religious element and the Christian ideals or philosophy which, until the Edwardian era, had a more marked influence than the classical philosophies. There has been a violent change with our traditions, and it is always desirable that in traditions the rate of change should be slow. This is one of the real reasons why the educated part of the community is proving unfitted to deal with the problems of to-day;

but it is important that the technologist, who would have to deal with human problems throughout his career, should also be able to bring a balanced outlook to bear on the questions of human relations or of administration with which he might be confronted. Prof. Garner maintained that properly taught engineering represents a complete discipline and a philosophy in the sense of the ability to see a particular field of knowledge in all its human relations. He protested strongly against the tendency to compartmentalize knowledge and stressed the opportunities which are offered by borderland subjects like physical chemistry. With an educational training in the humanities, science, both pure and applied, can be taught so as to enable one to be clear, logical and objective, able to interest people, to assess evidence, form reasoned judgments and explain them clearly to others. It is Prof. Garner's opinion that contact with industry in teaching applied science is essential and can with advantage be improved, especially where the training is being given in industry.

Scientific and Technical Man-power in the United States

The feature of No. 4 of *News Report*, issued by the National Academy of Sciences—National Research Council (Washington, D.C.; July–August 1951) is an article by Dr. M. H. Trytten, director of the Office of Scientific Personnel, on the 'Manpower Shortage in the United States". Analysing the intake available to maintain over a long period the projected military strength of 3·5 million men, Dr. Trytten points out that this figure has been achieved because of the existence of several groups—the pool of males without military service between the ages of eighteen and twenty six, personnel in military reserve status, and the career personnel. There are probably 750,000 career men now in the Armed Services; but to maintain a military strength of 3·5 million will require more than two years of service from all able-bodied youths, even without exemptions. With exemptions the average length of service of all youths not exempted must increase. Without exemptions the whole technology of the nation is in jeopardy. Meanwhile, the demand for technological personnel has mounted, and this summer more than twice as many scientific workers and engineers as were available could have been absorbed in research, production or teaching. It is also estimated that the output of scientific workers and engineers, even without the impact of the draft, is likely to decrease until at least 1955. In view of this situation the Director of Defence Mobilization has established a policy committee to make recommendations on all issues of policy affecting the handling of problems in utilizing scientific and technical personnel. The National Academy of Sciences appointed early in 1951 a committee to examine the situation; and it is believed that the recommendations of this committee, which were adopted by the Academy in April and included the establishment of a National Scientific Personnel Board in the Office of Defense Mobilization to study intensively all such problems, will receive careful consideration when the problem of specialized manpower is discussed.

The Scientific Outlook in 1851 and in 1951

This is the title of a Discourse delivered at the Royal Institution by Prof. H. Dingle last March, and reproduced as an article in the August issue of the *British Journal for the Philosophy of Science*. Prominence has been given at the recent Festival Exhibitions to the difference that science has made in practical affairs during the past hundred years. It is most fitting that there should be a permanent record of another aspect of scientific development, namely, the change in scientific outlook. In the first part of the article, Prof. Dingle emphasizes the basic assumption of the scientific men of 1851 that there was lying before them a world of material objects, moving about in space and time with, as Whewell maintains, a "*substance*, which stands beneath the apparent qualities and supports them". The reality of the substance was held to be its weight. Yet, as Prof. Dingle points out, it was the roundness and colour of Neptune, not its intrinsic property of weight, which was taken to be the guarantee of existence. The revolution that came in the twentieth century was simply the overthrow of that false notion of what science was and is; science itself has pursued the same undeviating course from Galileo through Newton and Einstein to our own time. The implications of the special theory of relativity are incompatible with any form of materialism. Prof. Dingle continues his argument to show the fallacy of the so-called philosophy of dialectical materialism. His treatment is both convincing and stimulating; the nineteenth-century disputes between science and religion are shown in perspective, and of possible further conflict he believes that the highest wisdom lies in recognizing both the relations between experiences and the very different values of the things related. "The discarding of old prejudice and the cultivation of a new outlook are not matters that can be completed in a moment". Prof. Dingle's article is a valuable contribution toward establishing this new outlook in place of dogmatic assertions of a hundred years ago.

Errors in the Carbon-14 Method of Archæological Dating

New lines of investigation are almost always welcomed with enthusiasm, more particularly when they involve disciplines in another subject than the one upon which they may throw light. It is a long time ago now since prehistorians were told all about their subject by human anatomists, and more recently the help of pollen analysis and the fluorine test has been readily accepted. Fortunately, the last two have been introduced to prehistorians by true scientific workers who have not failed to impress upon them the limitations and dangers of the new disciplines. Finally, there has appeared upon the scene the method of accurately dating prehistoric objects in years by analysing the percentage of the rare carbon-14 isotope present in material relative to the ordinary carbon-12. There is no doubt that this is a very valuable new method of study, and it has been taken up enthusiastically in the United States. Equally obviously, there are numberless factors, not perhaps all yet clearly understood, which may completely vitiate the results. A recent short article, only two pages in length, entitled "Radiocarbon Datability of Peat Marl, Caliche, and Archæological Materials", by H. H. Bartlett (*Science*, 114, No. 2951; July 20, 1951), describes just one such example. The author points out that when samples for study are taken from a site where alternating layers of marl and peat occur, the readings may be entirely erroneous owing to the presence of an unknown quantity of 'dead' carbon-12 derived from geologically ancient calcium carbonate;

this may dilute the equilibrated mixture of carbon-12 and carbon-14. Warnings like this do not, of course, invalidate the carbon-14 method of study; but they do impress upon us that we must be slow in accepting as infallible new methods of study until all the possible factors and circumstances bearing upon them have been considered and studied.

Forestry and Conservation in South Africa

In a recent issue of the *Journal of the South African Forestry Association* (Pretoria; No. 20, April 1951), under "Editorial Notes and Comments", there is a strong note on forestry and conservation which is equally applicable to a good many other parts of the world. The note points out that the South African forester and his activities are often condemned by his compatriots when in other countries they would be regarded as constructive and conservational. At one time or another, the forester has been accused of causing erosion, desiccation, destruction of the indigenous vegetation, of championing the exotic against the indigenous tree, of despoiling the beauty of the countryside with artificial plantations (some of these complaints have been heard in Great Britain) and so forth. The note continues to the effect that, so far as South Africa is concerned, if these accusations could be substantiated they would apply with a far greater force to the agricultural operations carried out in that somewhat arid land during the past half-century; this view is supported and expressed by the editor of the *Journal of the Botanical Society of South Africa* (Part 35; 1949) in the following words. "The effect of afforestation upon water supplies has been ably analysed and discussed by Dr. C. L. Wicht (Department of Forestry Bulletin No. 33; 1949). Much is still uncertain and awaits the results of experiments which are in progress. But it is clear, incidentally, that the relative importance of this subject has been much exaggerated when compared with the obvious flagrant and destructive results of much current agricultural and pastoral practice over great areas in the Union. The work of the Forest Department is mainly constructive and conservational; our farming methods are largely exploitational."

Artificial Insemination of Birds

The first Supplement Number of *The Onderstepoort Journal of Veterinary Research* (1951. Gov. Printer, Pretoria. 5*s*., overseas postage 1*s*.) is devoted to a valuable paper, 212 pages long, by G. C. van Drimmelen, on artificial insemination of birds by the intraperitoneal route. The paper discusses the historical background of this subject, its literature, and the author's own extensive work. There are three appendixes, one on the intraperitoneal method of insemination, one on the fowl cocks and the semen samples used, and the third on the post-mortem examination of the genitalia of hens. The bibliography, 11½ pages long, will be useful to all workers on this subject.

University of Leeds

It has been announced from the University of Leeds that the title of emeritus professor has been conferred upon Prof. R. Whiddington on his retirement from the Cavendish chair of physics. Dr. J. G. Wilson, senior lecturer in physics in the University of Manchester, has been appointed to a chair of physics at Leeds as from June 24, 1952.

The following lecturers (in the subjects and/or departments as shown) have been appointed: R. L. Holmes (anatomy), G. A. Mogey (pharmacology), K. G. Towers (veterinary officer and lecturer in veterinary hygiene in the Department of Agriculture), Dr. F. K. Sutcliffe (research lecturer in the Department of Colour Chemistry and Dyeing), and Dr. R. Reed (Department of Leather Industries).

The Night Sky in November

Full moon occurs on Nov. 13d. 15h. 52m., U.T., and new moon on Nov. 29d. 01h. 00m. The following conjunctions with the moon take place: Nov. 10d., 06h., Jupiter 4° S.; Nov. 24d. 11h., Mars 4° N.; Nov. 25d. 10h., Saturn 6° N.; Nov. 25d. 18h., Venus 6° N.; Nov. 30d. 14h., Mercury 2° N. In addition to these conjunctions with the moon, Venus is in conjunction with Saturn on Nov. 21d. 10h., Venus being 0·6° S. Mercury sets too soon after the sun during the greater portion of the month for favourable observation; the planet attains its greatest elongation east on November 28, and on November 30 sets nearly an hour after sunset, when it can be seen in the western sky for a short time. Venus, a morning star, rises at about 2h. 40m. up to the middle of the month, and at 3h. 20m. at the end of the month, with stellar magnitude −4 and the visible portion of the illuminated disk varying between 0·42 and 0·58. Mars is a morning star, stellar magnitude 1·7, rising a little before 2h. throughout November. Jupiter is visible throughout the night, setting at 3h. 45m. on November 1 and at 1h. 45m. on November 30, stellar magnitude −2·3; the planet is stationary on November 30, after which it has an eastward movement in the constellation Pisces. Saturn is a morning star, rising at 4h. 10m., 3h. 20m., and 2h. 30m. on November 1, 15 and 30, respectively, and is easily recognized a little south of γ Virginis in the early part of the month. Only one star brighter than magnitude 6 is occulted in November; on Nov. 10d. 17h. 40·6m., δ Piscium disappears (observable at Greenwich). The Leonid meteors, towards the middle of the month, which have been very feeble for many years, will be difficult to observe owing to moonlight.

Announcements

H.R.H. THE DUKE OF EDINBURGH has been elected an honorary fellow of the Institute of Navigation.

The Royal Society of New Zealand has awarded the T. K. Sidey Medal and Prize for 1951 to Prof. V. A. Bailey, professor of experimental physics in the University of Sydney, for "research in Radiation as bearing on Human Welfare". This Award is the most important made by the Royal Society of New Zealand by virtue of its international character. It was established to commemorate the passing by the New Zealand Parliament of the Summer Time Act, 1927, and was raised by shilling subscriptions, thus making possible a tribute by all to the value of the measure to human welfare.

The following appointments have been made in the University of Sheffield: Dr. T. H. Barton, lecturer in electrical engineering; Drs. W. H. Evans, H. C. Grimshaw, E. M. Guenault, W. C. F. Shepherd and F. V. Tideswell, to be honorary lecturers in mining. The John Stokes Research Fellowship has been awarded to Mr. H. L. Kornberg, who will work in the Department of Biochemistry; a Knoop Research Fellowship in Economics has been awarded to Mr. D. C. Corner.

A FAST CONTINUOUS ELECTRODIALYSER FOR HYDROPHILIC COLLOIDS, AND A FAST CONTINUOUS ELECTRODECANTER FOR HYDROPHOBIC COLLOIDS

By Prof. A. J. RUTGERS and R. SWYNGEDOUW
Laboratory for Physical Chemistry, University, Ghent

DURING the past three years, Dr. G. Jacobs[1] has carried out in our Laboratory researches on centrifugation potentials in colloidal solutions of arsenious sulphide; this sol can be prepared by passing a stream of hydrogen sulphide through a solution of arsenious hydroxide; no foreign electrolyte is produced, hence no dialysis is required. If we want, however, to extend these researches to other colloidal solutions, the difficulty arises that these sols cannot be prepared from base plus acid; they must often be prepared by a reaction like:

$$AgNO_3 + KI = AgI + KNO_3.$$

Thus an indifferent electrolyte (KNO_3) is formed, and dialysis is required in order to remove it. This takes time, especially if a considerable quantity of a highly concentrated sol is required. We have therefore constructed a fast continuous electrodialyser. This apparatus (Fig. 1) fulfilled expectations when used for the dialysis of hydrophilic colloids; if, however, hydrophobic colloids were handled in this apparatus, immediate electrodecantation occurred. We then decided to make a virtue of necessity, and to effect a separation of the hydrophobic sol into a dilute part and a concentrated part by electrodecantation; for this purpose the apparatus had to be duplicated in the direction of its longitudinal axis (Fig. 2).

The apparatus of Fig. 1 can be considered as a further development of a dialyser devised by Brinkman[2]; this dialyser consisted essentially of a glass tube around which a sausage skin fits. This system is placed in distilled water; dialysis takes place in the space between the glass tube and the sausage skin. We developed this apparatus into an electrodialyser (Fig. 1). Around the central glass tube we put first a platinum gauze, then a sausage skin, then a somewhat longer sausage skin; this system was placed inside a glass tube, which carried on its inner wall another platinum gauze. In this way we obtained an inner washing space, a space for the sol, and an outer washing space; feed and outlet pipes for each of these compartments could be fitted inside the central tube; they pierce its walls in the appropriate places. Molten paraffin is poured inside the central tube; after solidification it holds the numerous glass tubes firmly inside the central tube.

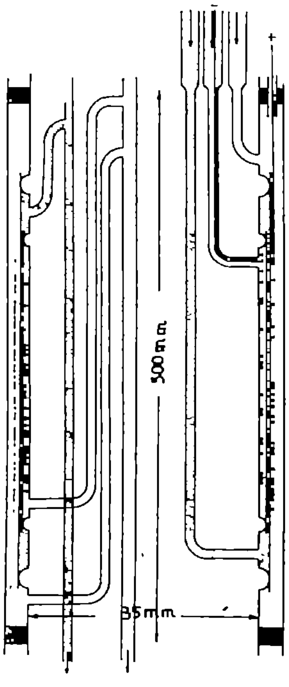

Fig. 1. Fast continuous electrodialyser for hydrophilic colloids

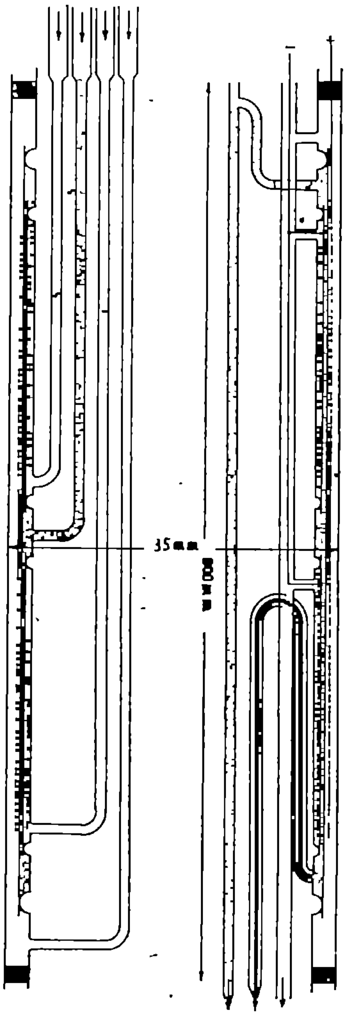

Fig. 2. Fast continuous electrodecanter for hydrophobic colloids

During dialysis, the counter-current principle is used. The sol enters at the bottom and leaves at the top; the washing water flows in the opposite direction. Hydrostatic pressure must be highest in the inner wash-chamber, medium in the sol-chamber, lowest in the outer wash-chamber. This can be obtained by giving a suitable shape to the outlet pipes.

With this apparatus (diameter of inner tube 38 mm., of outer tube 55 mm.; length of platinum gauzes 200 mm.), 200 cm.^{3} per hour of a hydrophilic sol could be freed from electrolyte (current density 3 m.amp./cm.^{2}; current about 0·7 amp.; voltage 100).

There is no reason for expecting the new apparatus to be efficient in removing non-electrolytes, such as urea; this was confirmed by experiment. It is unfortunate, for a simple apparatus capable of removing urea with good efficiency would be of great medical value (artificial kidney).

If a hydrophobic sol, for example, a silver iodide sol, is introduced into the apparatus shown in Fig. 1, electrodecantation occurs, and the concentrated sol sinks to the bottom, where it mixes with the freshly introduced sol. If the apparatus is slightly changed, so that the sol can be introduced at the top, it sinks rapidly to the bottom, and appears not to be dialysed at all; moreover, the liquid leaving the apparatus at the top always contains a considerable amount of silver iodide.

We therefore decided to duplicate the apparatus in the direction of its longitudinal axis (Fig. 2); the sol is introduced in the middle, at a speed of 200 cm.^{3} per hour; decantation takes place; the concentrated sol sinks to the bottom, while a liquid containing only a little silver iodide leaves the apparatus at the top; if electrolyte is carried off by this liquid, so much the better. The concentrated sol at the bottom is taken from the apparatus by a siphon-shaped capillary of 0·4 mm. diameter (a tap should not be used); it carries off 20 cm.^{3} per hour; this sol is about seven times as concentrated as the original sol. A litre of this concentrated sol can be prepared in two days; this quantity can be further dialysed in a Pauli dialyser in one operation, in order to obtain it free from electrolyte.

PREVENTION OF SWAYBACK SYMPTOMS IN LAMBS BY ADMINISTRATION OF COPPER SULPHATE TO THE PREGNANT EWE

By Dr. GEORGE DUNLOP
Animal Husbandry Dept., West of Scotland Agricultural College

In a previous paper[1] it was shown that the occurrence of swayback in lambs, which was enzootic on a hundred farms covering an area of forty square miles in north Derbyshire, could be prevented by the provision of copper to the pregnant ewes. In a later paper[2] control of the disease was obtained by the addition of copper to the diet of the ewes twenty days before the ewes began to lamb.

Recently Cunningham[3] has shown that the development of ataxia may be averted by regular drenching of the lambs with copper sulphate twice a week from birth until they are four months old. Each dose administered to the lambs consisted of 35 mgm. $CuSO_4.5H_2O$ (approximately 9 mgm. copper) in 0·5 oz. water. Administration of the doses was carried out on Monday and Friday of every week after the first lamb was born.

Bennetts found in 1937 that the disease was prevented by supplying copper to the mother before lambing occurs. Administration of a single dose of copper sulphate to affected lambs did not prevent development of the symptoms. Bennetts and Beck[4] showed that the feeding of copper to affected lambs arrested the progress of the disease.

Preventive measures for the control of the disease as it occurs in the west of Scotland have been studied for a number of years. Each year during March and April, farmers have reported to this Department that symptoms of the disease have appeared among the lambs in their flocks shortly after the commencement of the lambing season. This is usually the first indication that numerous cases of the disease will occur among the lambs yet to be born from the ewes in the flock.

Some method of control was desirable by which the ewes in the flock still to lamb would produce normal lambs which later would remain free from symptoms of swayback.

In 1940 and 1941 experiments were begun for testing practicable preventive measures; but during these seasons on low-ground farms there was no incidence of swayback in the experimental flocks. In 1942, 10 ml. of copper sulphate solution containing 200 mgm. copper was administered to each ewe still to lamb on one farm carrying Cheviot ewes which had been mated with a Border Leicester ram. The treatment was given one week after lambing had commenced in the flock, when a high percentage of the lambs already born had developed swayback. The incidence during previous years had also been appreciable. Following treatment of the pregnant ewes, no further cases of swayback occurred.

Similar results were obtained in another flock during the following year, while the original flock, in which the pregnant ewes were treated immediately before lambing commenced, showed no cases of swayback in the lambs.

The full results are presented in the accompanying table. This also shows experiences in other flocks subsequent to 1943. In these all the pregnant ewes after dosing gave birth to normal lambs. Ewes which were not treated produced a high percentage of abnormal progeny.

Treatment of Flocks susceptible to Swayback with Copper Sulphate

Flock	Year	No. lambing ewes	Date of treatment	Date lambing commenced	Per cent swayback during lambing in 1st wk.	2nd wk.	3rd wk.	4th wk.
A	1941	360	None	Mar. 14	13	8	14	17

E	1948	320	Mar. 8	Mar. 11	0	0	0	0
F	1948	100	Mar. 1	Mar. 11	0	0	0	0

In the west of Scotland it is now common practice to treat all ewes which may produce swayback progeny with copper at udder locking (within one week of lambing) or immediately swayback is observed in the lamb crop. One gram of copper sulphate dissolved in 30 ml. water is administered to each ewe.

No cases have been reported of the occurrence of swayback progeny in more than four thousand susceptible ewes treated in this way.

The administration of copper to the ewes immediately before lambing appears to provide complete control of swayback in the lamb crop on susceptible grazings.

THE *IN VITRO* FORMATION AND DISPOSAL OF CARBON MONOXIDE IN BLOOD

By TORGNY SJÖSTRAND

Laboratory of Clinical Physiology, Karolinska Sjukhuset, Stockholm

CARBON monoxide is constantly exhaled in human respiration, even when every possible external source of carbon monoxide is excluded[1]. It has also been shown that if blood is incubated at 38° C. for 10–24 hr., there is a constant increase of a factor which is determined as carbon monoxide. This increase is especially pronounced after hæmolysis[1,4].

This latter observation has now been confirmed and amplified in a further series of experiments (Table 1). In these investigations, the carboxyhæmoglobin concentration was determined by Horvath and Roughton's method[2], and also by the method described by Siösteen and Sjöstrand[3]. Both methods gave the same results within the respective experimental errors for the concentrations involved (0·1 per cent and 7 per cent carboxy-hæmoglobin).

Table 1. Increase in Concentration of Carboxy-hæmoglobin in Hæmolysed Blood after Incubation at 38° C. for 20 hr.

Method	Species	No. of separate exp.	Per cent carboxy-hæmoglobin before incubation (I)	Per cent carboxy-hæmoglobin after incubation (II)	$\frac{II-I}{I} \times 100$
Horvath and Roughton	Man	12	0·44	0·75	75
	Cow	6	0·50	0·97	94
Siösteen and Sjöstrand	Man	12	0·45	0·66	47
	Cow	10	0·51	1·05	100
	Pig	2	0·34	0·74	118

Therefore, it is possible to draw the following conclusions about the factor under investigation. (1) It is chemically combined with hæmoglobin. (2) It is liberated on oxidation of hæmoglobin to methæmoglobin. (3) It is oxidized at room temperature in the presence of hopcalite. (4) The heat liberated on oxidation corresponds to the heat of combustion of carbon monoxide. It has also been found that: (5) the factor is absorbed by solutions containing copper sulphate and cuprous chloride; and (6) it reduces $H_4[Si(Mo_2O_7)]$ in the presence of palladium chloride, according to Shepherd[4].

Carbon monoxide is the only substance known to have this combination of properties.

If the *p*H of the blood is changed before incubation, the formation of carbon monoxide is accelerated (Table 2). This effect is especially pronounced at *p*H 4–6 and *p*H 9–11. At more extreme *p*H's, however, the formation of carbon monoxide is inhibited.

Table 2. Increase in Concentration of Carboxy-hæmoglobin in Blood, hæmolysed by Addition of Distilled Water at Different *p*H Values after Incubation at 38° C. for 20 hr.*

Method	Species	Per cent carboxy-hæmoglobin before incubation	Per cent carboxy-hæmoglobin after incubation *p*H 4–6	*p*H 7·4	*p*H 9–11
Siösteen and Sjöstrand	Cow	0·69		1·35	2·60
	Cow		2·10	0·98	1·35
	Pig	0·84	2·20	1·10	1·70
	Pig	1·27	3·98	1·39	2·24
	Pig	1·00	3·79	2·20	3·95

* Changes of *p*H were obtained by using weak hydrochloric acid and sodium hydroxide solutions without the addition of buffers.

As may be seen from Table 3, the formation of carbon monoxide at *p*H 7·4 is greatly increased in the presence of 1/200 sodium azide, and the values are similar to those obtained after changing the *p*H of the blood. Thus, the comparative inhibition at *p*H 7·4 appears to be reversed by sodium azide.

Table 3. Increase in Concentration of Carboxy-hæmoglobin in Blood after Addition of Sodium Azide, 1 : 200, and Incubation at 38° C. for 20 hr.

Method	Species	No. of separate exp.	Per cent carboxy-hæmoglobin before incubation	Per cent carboxy-hæmoglobin after incubation without sod. azide	with sod. azide
Horvath and Roughton	Man	9	0·58	0·83	1·95
Siösteen and Sjostrand	Man	12	0·45	0·66	1·74
	Cow	2	0·85	1·20	5·20

The effect of different tensions of carbon monoxide on the formation of carbon monoxide in blood was investigated by adding carbon monoxide to the blood before incubation, to produce 5–60 per cent carboxy-hæmoglobin. In these experiments a significant decrease of the concentration of carboxyhæmoglobin was observed in nearly every case after incubation (Table 4). Table 5 shows, however, that in the presence of sodium azide there is an increase in carbon monoxide formation, even with increased tensions of carbon monoxide.

Table 4. Decrease in Concentration of Carboxy-hæmoglobin after Incubation at 38° C. for 20 hr. with Increased Carbon Monoxide Tension

Method	Species	No. of separate exp.	Per cent carboxy-hæmoglobin before incubation	Per cent carboxy-hæmoglobin after incubation
Horvath and Roughton	Man	11	12·05	10·91
Siösteen and Sjöstrand	Man	9	10·55	9·74
	Pig	4	39·2	35·0

Table 5. Change in Concentration of Carboxy-hæmoglobin in Blood after Incubation at 38° C. for 20 hr. with Increased Carbon Monoxide Tension, with and without Addition of Sodium Azide (1 : 200)

Method	Species	No. of separate exp.	Per cent carboxy-hæmoglobin before incubation	Per cent carboxy-hæmoglobin after incubation without sod. azide	Per cent carboxy-hæmoglobin after incubation with sod. azide
Horvath and Roughton	Man	8	12·50	11·46	13·84
Sjösteen and Sjostrand	Man	6	11·06	10·40	12·16

These observations seem to indicate that carbon monoxide may be both formed in and removed from the blood. If the blood is incubated at 38° C., an equilibrium seems to be reached between these antagonistic reactions. The rate of disposal of carbon monoxide is determined by its tension, and has its optimum value at approximately pH 7. In normal life the equilibrium may be affected by the expiration of carbon monoxide, if the concentration in the inspired air is lower than that of the alveolar air, as is usually the case with ordinary atmospheric air. It has also been shown that the reaction is shifted to give increased carbon monoxide formation during physical exertion and on breathing 10 per cent oxygen in nitrogen[5].

The results of these investigations appear to provide an explanation of the endogenous formation of carbon monoxide, and also of the observations made by Fenn and Cobb[6], Clark, Stannard and Fenn[7], and Clark[8], that carbon monoxide is oxidized in isolated muscle preparations and in the intact animal. They may also explain the well-known fact that the carbon monoxide capacity of blood is slightly greater than the oxygen capacity.

A more detailed account of these investigations will be published in *Acta Physiologica Scandinavica*.

SOCIETY FOR APPLIED BACTERIOLOGY

ANNUAL GENERAL MEETING

THE annual general meeting and conference of the Society for Applied Bacteriology was held in Marischal College, Aberdeen, during July 3–6. Approximately sixty-five members and visitors attended one or more of the four paper-reading sessions. At the meeting the resignation of the secretary, D. A. McKenzie, was announced and G. Sykes, of the Microbiology Division of Messrs. Boots, Nottingham, was appointed to succeed him. During the conference visiting parties were received at the Rowett Research Institute, the Macaulay Research Institute and the Torry Fisheries Research Station. Seventeen original papers and four demonstrations were presented at the four paper-reading sessions.

Miss M. J. Masson (Rowett Research Institute) described the microscopical methods used in a study of the gut of the sheep. The need for the use of direct microscopy as a preliminary to, and check upon, pure cultural and biochemical work on microbial populations was emphasized. Qualitative and quantitative changes in the microscopical appearance of contents from nine regions of the gut of a sheep fed with hay and a concentrate mixture and from the rumen of sheep fed with different diets were detailed. The isolation of *Clostridium butyricum* and lactobacilli from the rumen of a sheep fed with large quantities of flaked maize and small quantities of hay, and a Gram-positive streptococcus which liquefied gelatin, clotted milk, and later digested the clot, grew on McConkey's medium and survived 60° C. for 30 min., from the rumen of a sheep fed up to 300 gm. daily of casein, was reported.

Two papers on "The Chemistry of the Nitrifying Bacteria" were presented by Dr. H. Lees and Dr. T. Hofmann (Biochemistry Department, Marischal College, Aberdeen). The free energy efficiency of *Nitrosomonas* is usually taken to be about 6 per cent, but Dr. Lees has found that in the early stages of growth the value is about 50 per cent (biochemically a far more reasonable figure). The value falls rapidly as nitrite accumulates until, at nitrite concentrations of 1,500 μgm. nitrogen/ml., it has reached about 6 per cent. The rapid fall in efficiency may well be due to an increased respiration-loss consequent upon the maintenance of a low intracellular nitrite concentration in a medium of increasing nitrite content. Experiments on enrichment cultures of *Nitrobacter* have shown that the organism is highly sensitive to chlorate and that chlorate inhibition is reversed by nitrate; this accords with the results of percolation studies on soil. Dr. Hofmann, using the paper chromatography method of Fowden, has found that the amino-acid content of the protein of nitrifying bacteria does not differ fundamentally from the proteins of other less-specialized organisms.

Dr. James Shewan and his colleagues of the Torry Research Station discussed some aspects of the bacteriology of marine fish. The taxonomy of the groups present in marine fish is one of great difficulty, and a comprehensive study of these groups is at present being carried out. It has been found, for example, that it is very necessary, in order to explain different rates of spoilage in the same fish caught at the same time and handled and stored under identical conditions, to know not only the number but also the types of bacteria present. The three main families of bacteria found are Achromobacteriaceæ, Pseudomonadaceæ and Micrococcaceæ. The important species in these groups also show certain common characteristics, namely, capacity for growth in low concentrates of organic nutrients, enhanced growth on solid surfaces (presumably due to increased concentrates of organic nutrients on the solid surfaces), fairly low optimum temperatures (20°–25° C.) and marked heat sensitivity; they are actively proteolytic and usually weakly saccharolytic. Some have rather unusual biochemical characteristics, for example, liquefaction of agar, digestion of chitin and reduction of trimethylamine oxide; a few are luminescent.

A symposium on the chemistry and bacteriology of silage was presented during the conference. Dr. A. J. G. Barnett (Marischal College, Aberdeen) reviewed some recent studies on the estimation of the lactic acid content of silage and directed attention to the fact that, while the lactic acid content of silage is directly related to pH, if the amount of lactic acid is re-calculated on the basis of the dry-matter content of the fresh silage, a similar curve results indicating that the lactic acid formed is proportional to the dry matter content of the initial crop. In further work, at present in progress, Dr. Barnett is studying the change of pH in relation to the lactic acid increase and the decline in sugar content.

Mrs. A. C. Stirling (College of Agriculture, Edinburgh) presented the results of preliminary experiments with grass silage made in laboratory containers under controlled conditions. Investigation of the bacterial content of such laboratory silage indicates that the fermentation proceeds more quickly at 30° C. than at 22° C. and that a temperature of 40° C. is selective of different types of organisms. Wilting of the grass delays bacterial action, whereas maceration gives a more rapid fermentation and a lower pH.

Miss R. E. A. Allen and Miss A. B. Dickinson (King's College, Newcastle upon Tyne) have investigated the variation in pH and total bacterial count (microscopical) in a pit of unmolassed grass silage. While they stress that it is not possible to draw final conclusions from the examination of a single pit, from their results it would seem that the variation of quality of silage in a pit, as measured by pH, is greater from top to bottom than from side to side. This agrees with the findings of Dudley and Townsend on the variation of crude protein and dry matter content through a cylindrical silo. Miss Allen's and Miss Dickinson's results were of interest in demonstrating the constancy of pH found in the middle layer of the pit.

Some preliminary results and suggestions on the role of plant cells in the ensilage problem were described by L. A. Mabbitt (Edinburgh). His paper dealt primarily with the problem of producing an apparatus which would be capable of doing all operations from sowing the seed to ensiling the fodder in the same sterile chamber. The illustration of Mr. Mabbitt's apparatus created considerable interest. Bacteriological examination of material obtained during 1950 showed that the 'silage' was sterile. Chemical analysis of the material showed that no alcohol, no volatile acid and no lactic acid were present. The amino-acid and volatile base content showed an increase. This work is also continuing.

The enumeration of lactobacilli on grass and silage has been studied by R. M. Keddie, Edinburgh. Mr. Keddie has found that addition of oleic acid and later 'Tween 80' stimulated the growth of lactobacilli. A medium containing 'Tween 80' and acetate in the form of an acetic acid/sodium acetate buffer was used at a final pH of 5·4. The medium gave good growth of lactobacilli apart from a group of homofermentative species. It is hoped from this preliminary work to develop a medium suitable for the enumeration of lactobacilli on grass and silage.

The methods hitherto used for the study of the anaerobic bacterial flora of silage have not been satisfactory. The development of an improved technique has been undertaken by R. F. Rosenberger (Edinburgh). Through the work of Barker in California the problem of the anaerobic fermentation of lactate has been largely solved, and, basing his work on Barker's conclusions, Mr. Rosenberger has been able to evolve a dilution method which appears to enumerate quantitatively the number of vegetative cells and spores of anaerobic lactate fermenters such as occur in normal silage. A similar method is being developed for the proteolytic anaerobes, based on the ability of these organisms to carry out an extensive protein breakdown in the absence of any other energy source, provided oxygen is excluded. With the introduction of semi-solid media and non-toxic reducing agents, thioglycollic acid and cysteine, a great advance has been made in anaerobic technique.

Dr. M. Ingram (Cambridge) recalled that experiments on whales have shown that the anaerobic bacteria (*Cl. welchii* type A) which occur naturally in whale flesh do not begin to develop actively until the muscles have passed through rigor mortis. Attempts to observe this effect on more normal meat (horse) have so far been unsuccessful, whether the flesh was incubated anaerobically with *Cl. welchii* as in the whale (artificial inoculation was necessary) or aerobically with species of *Pseudomonas*.

Some preliminary results on a small chlorinating plant suitable for farm water supplies were presented by Dr. L. F. L. Clegg (Wolverhampton) and W. A. Cuthbert (Leeds). The paper discussed the possibility and practicability of improving by chlorination those farm supplies used for dairy purposes which were either potentially dangerous or of such poor bacteriological quality as to be liable to affect the keeping quality of the milk produced. So as to overcome the difficulty of variation in the organic matter content, which in turn would cause a variation in the chlorine demand, super-chlorination followed by de-chlorination were employed. The principle of dosage was that of drawing in concentrated hypochlorite solution by a vacuum pump through a Venturi tube, followed by de-chlorination, on the same principle, with sodium thiosulphate. Incomplete sterilization was afforded with a dosage of 10 parts per million and a contact of 90 seconds, but satisfactory results were obtained by dosing at both 5 and 10 p.p.m. with a contact of 6¼ minutes. In order to reduce contamination from the sodium thiosulphate solution itself, it was found necessary to add a by-pass from the contact tank so as to leave a residual of 0·1–0·2 p.p.m. of available chlorine. Experiments are continuing using soil suspensions as contaminating material, and it is intended to study a prototype plant under farm conditions.

Two new experiments with the methylene blue test were described by H. Barkworth (Derby). In Mr. Barkworth's results, with replicate samples, the reduction time of methylene blue in milk diminishes with storage time, but this relationship ceases, or at least is seriously modified, when the reduction time has fallen to 30 min. These results cast suspicion on the value of any routine methylene blue test with an original reading of 30 min. or less, and since in the majority of cases tubes are read only at half-hourly intervals this means that any original reading less than one hour is of doubtful value.

Improvements in the ion-exchange method of preparing silica gel media (Taylor) was the subject of a communication from W. K. Smith (Butterwick Research Laboratories, Welwyn). This type of medium has a number of advantages and has created widespread interest. Mr. Smith discussed problems in the preparation of such media and described further applications.

The need for a rapid *in vivo* screening test for compounds of possible antituberculous activity has held the attention of workers in this field for some considerable time, and because of their small size, resulting in economy of drug and cost of maintenance, much work has been done on experimental tuberculosis in mice. Miss Betty Croshaw (Boot's, Nottingham) dealt with attempts to standardize the screening test in mice using intracerebral infection, all results being based on the extent of lung tuberculosis when the experiments were deliberately terminated four to six weeks after infection. Miss Croshaw's paper also dealt with the virulence of cultures according to the type of culture medium used and the advantage of objective interpretation of drug activity (that is, survival-time).

A note on the bacteriology of yoghurt was given by Miss E. R. Hiscox (Reading). It would appear that this fermented milk consists primarily of a mixture of *Lactobacillus bulgaricus* and *Streptococcus thermophilus*. In some types yeasts may also be present.

Miss C. M. Cousins (Milton-Deosan, London) described a preliminary screening test (bacteriological) for quaternary ammonium compounds and formulations. The test is based on a plate count method which determines the survival of a given test organism, *Bacterium coli*, in sterile homogenized whole milk, added with the bacterial suspension to the quaternary ammonium compound dilutions, for an exposure time of two minutes. The paper directed attention to the special cleaning of glassware that is necessary. The preparation and use of the quaternary ammonium compound inhibitor, lecithin in 'Lissapol N', was described, with details of the testing procedure. Examples quoted showed how this test indicates a difference in bactericidal efficiency between (*a*) two different quaternary ammonium compound solutions, and (*b*) the same quaternary ammonium compound included in two powder formulations of differing *p*H value.

GENES AND MUTATIONS

THE Symposia on Quantitative Biology held annually in the Biological Laboratory at Cold Spring Harbor, Long-Island, have become a major event in biology. Their purpose is to foster a closer relationship between biology and the other basic sciences, and they set out to achieve this not only by attempting a synthesis of existing experimental data concerning a particular subject, but also by applying new knowledge gained in other fields.

This year, the sixteenth of the series, the topic of discussion, selected by Dr. M. Demerec (Carnegie Institution), was "The Genes and Mutations". The same subject was discussed ten years ago, and the present meeting was intended to show the advances made in genetical research during the past decade. In 1941 the main subjects of discussion were the giant chromosomes of the salivary glands of *Drosophila*, the mechanism of chromosome coiling and spiralization, and the quantitative aspect of spontaneous and radiation-induced mutations. Only one contribution was concerned with the genetical usefulness of micro-organisms, viruses and bacteria. During the present Symposium the latter occupied a prominent position, and it was clearly demonstrated that the knowledge gained from studies of the genetical behaviour of bacteria, viruses and bacteriophage has deepened our understanding of the basic fundamentals of genetics themselves, and explained phenomena which baffled geneticists of ten years ago—as was so dramatically illustrated by T. M. Sonneborn (Indiana University) in the closing session.

A new theory of the gene, including its action in development and its relation to other genes, was brought to light by the work of B. McClintock (Carnegie Institution). She described very remarkable and complicated results on mutable genes in maize, which can be interpreted as due to transposition of minute pieces of chromatin from one position to another in the chromosome. The frequency of such transposition is itself under genic control, which findings emphasize the close integration or interrelationship of the gene complex. According to R. Goldschmidt (Stanford University, Cal.) the gene in the chromosome represents a "field of action" closely integrated into one system, in which gene mutation is a consequence of rearrangements on a submicroscopic scale. L. Stadler (University of Missouri) presented results on spontaneous gene mutation in maize, and E. R. Lewis (California Institute of Technology) on pseudoallelism in *Drosophila*. Both contributions have shown how it is possible by exact and extremely detailed genetical analysis to obtain insight into the complexity of genic activity. The same point was emphasized by S. G. Stephens (University of North Carolina) in describing the diversification of individual genetic loci in the diploid and amphidiploid forms of *Gossypium*.

Gene action and gene–enzyme relationship was discussed by D. M. Bonner (Yale University) and N. H. Horowitz (California Institute of Technology) in *Neurospora*. It was argued that there are genes which control only one step in the synthesis of enzymes, but an example in the synthesis of nicotinic acid was also presented to show that the blockage can be incomplete.

The genetical impact of chemical agents on genes and chromosomes was but little known in 1941. However, the present conference showed that the wealth of results obtained meantime in diverse organisms by the study of a great array of substances is not only impressive but also has widened our concept of mutagenesis itself and brought to light phenomena not observed previously. C. Auerbach (University of Edinburgh) pointed out the differences between chemically and X-ray induced mutations, by studying the mosaics in *Drosophila*, and emphasized the possibility of a delayed effect on the gene. Dr. Demerec described tests of various highly mutagenic compounds on the streptomycin-dependent mutant of *Escherichia coli*, which is a particularly suitable object for studies of the influence of environmental factors on gene-stability. On this aspect more evidence was presented by A. Hollaender (Oak Ridge National Laboratory, Tenn.) and collaborators, showing that lack of oxygen is one of the factors which greatly reduces the mutagenic effect of chemical agents and ionizing radiations. M. Westergaard (Institute of Genetics, Copenhagen) described his 'back-mutation' test in *Neurospora*, which will prove to be a very useful and rapid method for the detection of chemical mutagens, and made an attempt to interpret the chemical basis of induced mutagenesis. The aspect presented by Westergaard linked up closely with the contribution of N. H. Giles (Yale University), who described the various mechanisms which may be responsible for the spontaneous reversions of biochemical mutants in *Neurospora*.

The visible effects of various chemical agents on the chromosomes of *Allium* and *Vicia* were described by A. Levan (Institute of Genetics, Lund), who demonstrated that different chromosome regions may exhibit a different degree of reactivity to a drug, suggesting that further investigation by genetical and cytological means may disclose specific affinities between certain chemical compounds and chromosome regions or even genes.

The broader evolutionary significance of mutagenesis was discussed by A. Gustafsson (Forest Research Institute of Sweden, Stockholm), who illustrated, with examples on barley, how new mutants produced artificially can be superior to the original type under different environmental conditions. W. L. Russell (Oak Ridge National Laboratory, Tenn.), by using an ingenious method of analysis, was able to present data obtained from about 85,000 mice, which show that the X-ray induced mutation-rate is at least fifteen times higher in this mammal than in *Drosophila*. Because of the great likelihood that man belongs more to the former than to the latter type in respect of radiation sensitivity, Russell's data add to the problem of radiation hazards in man a very serious emphasis, which was stressed by Prof. H. J. Muller.

The genetic composition of a population is known to be under the influence of various factors, such as mutation, selection, rate of reproduction, etc. A. Novick and L. Szilard (University of Chicago) have described the 'chemostat', which makes the study of these factors possible in bacteria. It is an apparatus in which the medium is automatically replaced so that the various growth-limiting factors may be added at a slower or higher rate than the reproduction of the bacteria. These workers illustrated with experimental observations the usefulness of the chemostat in genetical investigation, the results obtained being similar to those of K. C. Atwood (Columbia University) and co-workers employing the more conventional method of genetical analysis.

The Symposium devoted one session to the cytoplasmic constituents of heredity. P. L'Héritier (University of Paris) has proved that the sensitivity of *Drosophila* to carbon dioxide is due to a cytoplasmic factor, and closely resembles a virus-caused infection. He was able to show that by injecting extract from carbon dioxide-sensitive flies into resistant *Drosophila*, the latter 'acquired' carbon dioxide sensitivity. When the 'virus' or 'genoid' invades the germ-plasm, then the carbon dioxide sensitivity becomes a heritable property. L'Héritier favours the view that the 'genoids' have an internal origin. A more complex system of cytoplasmic inheritance was presented by B. Ephrussi (University of Paris) in yeast. He finds that the formation of large and small colonies, which differ also in the presence or absence of cytochrome-oxidase, is due to a nuclear gene, inducing an instability in the cytoplasm. The latter can be influenced or affected by environmental factors, such as the presence of trypoflavin in the medium, when the incidence of small-colony formation increases enormously.

A large part of the Symposium was taken up with the genetics of bacteria and bacterial viruses. J. Lederberg (University of Wisconsin) and co-workers gave a detailed review of bacterial genetics, derived from experiments with *E. coli*, line K.12. Lederberg pointed out the complex system of linkage relationships of known genetic loci in this bacterium. The inherent difficulties of bacterial heredity were further stressed by E. M. Witkin (Carnegie Institution), who analysed the method of segregation and recombination in multinucleate bacterial cells. The cytology of bacteria was presented by K. A. Bisset (University of Birmingham) and E. D. DeLamater (University of Pennsylvania). Their papers brought out the basic disagreements in the interpretation of the cytological phenomena, and further emphasized the difficulties of bacterial genetics.

The transformation of various morphological and serological types of pneumococci by deoxyribosenucleic acid extracted from particular mutants was reviewed by H. Ephrussi-Taylor (Institute of Genetics of the C.N.R.S., Paris), who presented new results suggesting that the 'old' genetic determinant is not only altered but is completely replaced by the 'transforming principle'. R. D. Hotchkiss (Rockefeller Institute of Medical Research) has induced penicillin-resistant pneumococci which have yielded another 'transforming principle' (deoxyribosenucleic acid), and was also able to show that by combining this with the morphological 'transforming deoxyribosenucleic acid' they 'segregate' independently. Another interesting case of transformation has been found by N. Zinder (University of Wisconsin) in *Salmonella*, in which a 'stimulating' substance must be liberated first, in order to produce the transforming factor itself. It is claimed that the latter is associated with the microsomes of the cytoplasm.

The various properties of bacterial viruses and their behaviour in heredity were described by S. E. Luria (University of Illinois) and A. O. Hershey (Carnegie Institution). It has been shown that genetical analysis is still the most powerful method by which not only the characteristics but also the organization of the bacteriophage itself may be studied. At the same time it has been possible to demonstrate in these 'simple' forms many of the features of a complex genetic system, such as exists in higher organisms. However, they also show other phenomena, such as 'phenotypic mixing', which at present remain unexplained.

The Cold Spring Harbor Symposium was an outstanding success since it brought together into a coherent and closely integrated system a great deal of new and fundamental information, obtained from studies on the most diverse organisms. It has emphasized two facts: first, genetics is making use of many new organisms and techniques and is thus at present extending its boundaries extremely rapidly and to great profit; and secondly, and consequent upon the specialization which is necessarily occurring, it becomes increasingly desirable to hold meetings such as this, at which the new fields may be integrated.

SECOND INTERNATIONAL CONGRESS ON ASTRONAUTICS

THE second International Congress on Astronautics was held in London during September 3–8. It was attended by nearly fifty delegates representing societies and groups interested in astronautics from Argentina, Austria, France, Germany, Great Britain, Italy, Spain, Sweden, Switzerland and the United States. The first International Congress, held in Paris in September 1950, was purely exploratory in nature and was intended as a series of informal meetings to discuss the possibility of setting up an international federation. As a result of the deliberations of the first two days of the recent Congress, an International Astronautical Federation was founded, "to promote and stimulate the achievement of space-flight". Dr. Eugen Sänger was elected president, and the two vice-presidents are Dr. G. Loeser, of the Gesellschaft für Weltraumforschung, and Andrew G.

Haley, of the American Rocket Society. The headquarters are to be in Switzerland, and the Swiss group (there is as yet no legally constituted society) will handle all international matters, such as the collection, classification and storage of an astronautical library and archives. It is envisaged that the Federation's main tasks will be in the exchange of information between member societies and the organization of technical congresses. The next congress will be held in Germany in 1952.

The latter part of the London Congress was devoted to a symposium of papers on the general theme of orbital vehicles, their construction and uses. There was general agreement among the speakers that such vehicles are possible from an engineering point of view; the first instrument-carrying vehicles could be built within ten to fifteen years; but man-carrying artificial satellites appear to be much further in the future. In all, seventeen papers were read dealing with the engineering problems of raising and constructing such vehicles, return to earth by high-speed glider, travel between artificial satellite orbits, radar tracking of vehicles from the earth, danger from meteors and other relevant topics.

Mr. T. Nonweiler dealt with the problem of descent from a satellite orbit by glider. The most difficult matter is the temperature reached during the descent. In general, the rate of heat transfer to a body moving at very high speeds cannot be accurately calculated. However, Mr. Nonweiler presented an approximate general solution which he has developed and which is applicable at Mach numbers of 10 or more if the Reynolds number is between about 10^4 and 10^6. A return glider would, in fact, be operating within these limits during the greater part of its flight time. The effects of the air slip at the wing surface have also been examined; this has led to an estimate of the maximum rate of heat transfer to the surface. A limit to the skin temperature is also imposed by the conduction of heat along the surface: this has also been calculated. It was shown that the wing surface temperature will be a minimum if a thin, double-wedge wing-section is used, with a position of maximum thickness well aft and with both its inner and outer surfaces acting as good radiators of heat; the temperature will be highest near the leading-edge of the wing undersurface, and its value will vary approximately as the fourth root of the wing loading. If a maximum skin temperature of 1,300° C. be allowable, then it should be possible, for example, to construct an all-wing delta planform aircraft with an all-up weight of 20-tonnes capable of accommodating a payload of 5 tonnes.

In a paper entitled "Meteor Hazards to Space Stations", M. W. Ovenden extended both his own earlier work[1] and that of Grimminger[2]. Grimminger considered a space station of about 100 sq. m. exposed area and calculated the probable times between collisions with sporadic meteors of various magnitudes. The astronomical factors affecting the validity of Grimminger's analysis were examined. The existence of iron meteors was shown to require a reduction in the collision times by a factor of about 2. Radar observations provide direct evidence for the relationship between the assumed number of meteors to their magnitude down to magnitude 7, but extrapolation beyond this limit is uncertain because processes exist which might disturb the distribution. One such process is the sun's radiation pressure, which would repel all meteors smaller than magnitude 30 out of the solar system. Another process affecting much larger meteors is the Poynting–Robertson effect. This may increase Grimminger's times by a factor of about 3, although a much greater possible increase cannot be ruled out. The danger from meteor showers is comparable with that from sporadic meteors. The greatest uncertainty in the estimates of collision times is due to the imperfect knowledge of the mass of a meteor of given magnitude. Error here may require, at worst, a decrease in collision times by a factor of 50. The use of a very thin 'meteor bumper' around a space station, which would explode any incident meteors, was suggested for space stations intended for use for a period of more than about a year.

The greatest problem of interplanetary flight is that of propulsion, and in his paper "Interplanetary Travel between Satellite Orbits", Prof. Lyman Spitzer discussed a method of applying nuclear energy. It was suggested that an electrically accelerated ion beam could be used for achieving a gas ejection velocity of 100 km./sec. without the use of very high temperatures in the propellant gases. Such a unit could not be built with a large enough thrust/weight ratio to allow it to take off from the surface of a planet. It would be capable of travelling from a close-orbital station about the earth to a similar orbit about any other planet. The mass flow of the working fluid in an ion rocket would be low, and hence interplanetary vessels of a very low mass ratio could be built.

In "Biological Problems of the Earth Satellite Vehicle", Médecin-General P. Bergeret discussed the conditions under which the human body would have to function in an artificial satellite. One of the major unknowns is the effect of zero *g* or 'free fall' conditions. This condition can be obtained for periods up to 10 sec. in high-speed jet aircraft. Artificial gravity may be necessary and this can be obtained by rotating the vehicle.

STRESS ANALYSIS

THE fifth annual conference of the Stress Analysis Group of the Institute of Physics was held during April 4–6 in the Mechanical Engineering Laboratory of the University of Liverpool. Papers were read on relaxation methods, fatigue, applications of electric resistance strain-gauge methods, brittle lacquer methods, a pneumatic strain-gauge, applications and problems of the 'frozen stress' method of photoelasticity, and hydraulic methods of applying test loads.

The opening lecture of the conference was given by Prof. D. G. Christopherson on "Numerical Methods in Stress Analysis with Special Reference to the Relaxation Method". He outlined the development of the application of numerical methods to stress analysis problems, emphasizing the different approach of the mathematician and the engineer. The mathematician faced with an insoluble differential equation or an unreasonably large number of simultaneous linear equations seeks for more rapid means of obtaining an approximate solution. The engineer, on the other hand, concerned in the first place with problems of complicated structural frameworks, rejects the traditional apparatus of analysis and seeks for help in processes in which experience, intuition and imagination about the probable behaviour of the structure can play as large a part as mathematical ability. Prof. Christopherson referred to the moment-distribution method of Hardy Cross as one such method. Sir Richard Southwell's relaxation method was also first applied to problems of frameworks, and although the greatest successes of the relaxation method have been won in fields remote from structural engineering, the nomenclature of the method still shows its original applications.

Prof. Christopherson dealt with several types of problems of importance in stress analysis, demonstrating how they can be tackled, how the accuracy of a solution can be improved or at least reliably estimated, and how previous experience or intuitive knowledge of the type of stress distribution to be expected can all be made to give a more rapid convergence and therefore a quicker solution.

The two papers dealing with electric resistance strain-gauge work were by P. H. Wolfenden, on the use of these gauges for the measurement of transient forces in power looms, and by R. G. Boiten, on the determination of residual stresses, respectively. The latter dealt with the problems encountered when it is not possible to take the structure under investigation through a loading cycle while the gauges are in place. This arises mainly when determining stresses due to the self-weight of a structure such as a bridge, and when investigating locked-up stresses such as those due to welding. The method described by Mr. Boiten consists essentially of the measurement of the change of stress around a circular area 6 mm. in diameter. Three gauges are placed radially as close as possible to the area, which is then removed by drilling a hole of that diameter. From the change of stress observed the original locked-up stresses can be computed on the generally sound assumption that the stresses are reasonably uniform over the small circular area. Considerable care under what must often be field rather than laboratory conditions is required in the placing of the gauges and the hole.

Dr. D. G. Sopwith, in a lecture on "Fatigue", dealt with the subject of the failure of components or structures under repeated loads from the point of view of the designer or stress analyst rather than that of the metallurgist. He discussed the correlation of the safe stresses under fatigue conditions with other physical properties of the material and also the influence of factors such as temperature and corrosion on the behaviour of a specimen subject to repeated loading.

Dr. A. W. Hendry and J. K. Tattersall, and G. Robertson described work they have done using the 'frozen stress' method of photoelasticity, which makes use of a phenomenon observed in certain photoelastic model materials—namely, that a model subjected to load and taken through a heating and cooling cycle retains the relevant fringe pattern after the load has been removed and can even be sliced without the resulting slices losing their 'frozen' pattern. Dr. Hendry and Mr. Tattersall have used the method to analyse the stresses in a buttress dam of a hydroelectric power scheme in Scotland. They dealt separately with the stresses induced by the water pressure and those due to the weight of the dam. The former were tackled by ordinary 'frozen stress' methods using 'Catalin' as their model material. The latter posed a more serious problem since none of the usual photoelastic model materials capable of being sliced is sufficiently stress-optically sensitive to show fringes under its own weight. To simulate a gravitational field using a centrifuge necessitated the use of the longest convenient rotor arm so that the body force on the model should be reasonably uniform throughout the depth of the model. This made it impossible to spin the model in the oven as is usual; it would have involved the use of an impossibly large oven. To overcome this difficulty the model was heated in an oven and then transferred very rapidly in a heat-insulated box to the centrifuge, where it cooled slowly while being spun.

Mr. Robertson's work dealt with the stresses in pipe flanges. He used the comparatively new American material 'Fosterite', with which he could find no fault apart from its very high cost. He overcame one difficulty which is inherent in the analysis of three-dimensional problems by the 'frozen stress' method, this difficulty being that the slices cut from the three-dimensional models should be as thin as possible, as they are treated afterwards by the methods of two-dimensional photoelasticity. Very thin models, however, display very few fringes, since the fringe order at a point is proportional to the thickness of the model as well as the principal stress difference. Thin slices, therefore, require accurate measurements of fringe order by compensator methods. Having had to deal with a solid of revolution, Mr. Robertson was in a position to cut a large number of radial slices which by symmetry were identical. He made these slices thin enough to meet the requirement that the stresses should be reasonably constant through the thickness of the slice, but obtained satisfactory fringe photographs by using a pile of half a dozen or more slices superimposed on each other. The fringe photographs obtained in this way were strikingly well defined.

H. de Leiris discussed the development of brittle lacquer methods and of a pneumatic strain-gauge of very short gauge-length. He compared the fusion technique of applying strain-sensitive lacquers with the dissolving technique exemplified by such commercially available lacquers as 'Stresscoat' and 'Strainlac'. He discussed the relative merits of using different criteria such as the appearance of the first crack, the crack density or the lengths of the cracks when interpreting crack patterns. He dismissed the first two criteria as unsatisfactory, being dependent on variations in the thickness of the lacquer and other fortuitous circumstances. He was in favour of the method by which a family of curves, one for each increment of load, is obtained by drawing a line through the extremities of all the cracks. This method has the merit of dealing with a large number of cracks each time, thereby eliminating the effect of some of the random variations. M. de Leiris emphasized the important part played by the contraction stresses in the lacquer which are present before any load has been applied to the specimen. The load is, in fact, only the proverbial last straw which makes the lacquer crack. He therefore found it difficult to envisage any mechanism of failure which did not in some way require a tensile stress to open the crack. No simple law of cracking has as yet been suggested. There is, all the same, no doubt that the brittle lacquer method used as an auxiliary to more accurate methods of analysis fulfils an important function. In the second part of his paper M. de Leiris described a pneumatic gauge operating on the 'Solex' principle. This instrument has a gauge-length of 2 mm. with a magnification of 200,000; a stress of 1 kgm./sq. mm. in steel is indicated by a change of level of 20 mm. on a manometer.

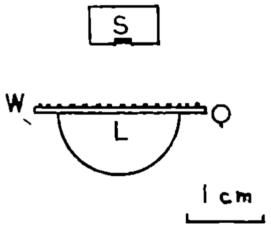
Chemical Effects in Liquids due to α-Particle Irradiation

A considerable amount of research has been carried out on the chemical effects which are produced by alpha-particles in liquids. So far, no satisfactory theory has been proposed to account for the fundamental processes involved in these reactions. From early studies, extended by recent work in this Department, of the ionization currents which can be collected from liquids, it is clear that the vast majority of ions recombine almost immediately. Jaffé[1] has shown in his 'column theory of ionization' that in liquids the half-life for recombination is 10^{-7} sec., due to diffusion alone. It has been pointed out by Kramers[2] that, due to the intense electrostatic fields which must exist in such columns of ionization, the half-life should be substantially reduced. It therefore appears impossible to explain the main features of the chemical experiments simply in terms of the production of ions, especially in view of the independence of chemical yield upon concentration of the reactants.

It has already been reported that quanta are emitted from thin films subjected to α-particle bombardment[3], and we considered that the chemical effects might be due, at least partly, to quantum emission associated with the intense ionization. As in the experiments with thin films, this radiation would be readily absorbed by the parent material, possibly producing free radicals within the solvent. While the radiation length is small compared with the bulk of the liquid, it is large compared with the estimated diameter of the ion columns. In this manner, the production of free radicals can be distributed over a comparatively large volume, hence increasing the probability of producing chemical effects remote from the ionic column and independently of ionic recombination. Such a basic process would provide a mechanism for the independence of concentration of reactants and the chemical yield. Experiments were therefore conducted with the view of testing such a theory.



The experiments took the form of irradiating a thin film of water with α-particles. A sample of a suitable aqueous solution was exposed to the quanta which might be liberated from the thin film. The diagram shows the experimental arrangement. The source *S*, about 20 millicuries of polonium, was placed about 0·5 cm. above a quartz slide 1 mm. thick. A film of water, of a thickness less than the equivalent range of the α-particle, was maintained on the upper surface of the slide. A reaction vessel, *L*, containing about 1·5 c.c. of solution, was placed immediately below the slide. The solutes investigated were ferrous ammonium sulphate, chloracetic acid and sodium iodide; in each case the solvent was water. Colorimetric methods were used for determining the yields of ferric, chlorine and iodine ions respectively. The water films were subjected to α-particle irradiation for periods of up to eleven days. Control experiments were performed to determine the amount of chemical change due to other conditions and due to the irradiation of the quartz by α-particles. Such control effects were in general negligible. Experiments were also carried out in which similar solutions were irradiated directly by α-particles.

A comparison of the results showed that chemical effects, between a twentieth and a twenty-fifth of the yield obtainable from direct bombardment, were found when the thin water films were irradiated. Recent improvements of the measurements reported previously[3] have provided an estimate of the absorption length of the quanta in the thin films. It appears that the ratio of the numbers of quanta emerging from the thin films in the above chemical experiments to the total number of quanta produced by the α-irradiation is of the same order of magnitude as the above ratio of the two chemical yields. These results suggest that the bulk of the chemical effect produced by α-particles in liquids can be explained by secondary effects of quantum emission arising from the primary ionization.

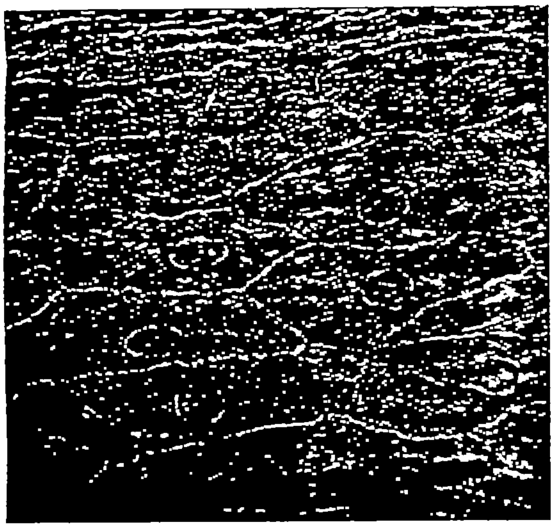
Surface Cells of Feather Barbs

From Strong's[1] drawings it is evident that those cells of the cortex of the feather barb which lie nearest to the surface are flattened. No author, however, has directed attention to the fact that these cells differ in structural detail from the rest of the cortical elements. The surface cells of the feather barbs appear to form a pattern similar to some of the cuticular scale patterns seen on animal hairs. It was found that this pattern could be shown by making casts of the barbs in the same way as casts of animal fibres are made.

These casts were made in polyvinyl acetate; a thin layer of a 20 per cent solution of polyvinyl acetate in benzene was spread on a microscope slide and heated to drive off the benzene. Feather barbs were then placed on the plastic layer and another slide placed on top; these slides were then placed on an electric hot plate and pressure applied (the load applied was approximately 6 lb. over the whole slide). A small piece of polyvinyl acetate was placed on another slide adjacent to the first slide and used as a temperature guide; when it had softened the current was switched off, the slides were allowed to cool while still under pressure, and the barbs afterwards removed from the slides and the casts exam-



Cast near base of barb of Guinea fowl. × 400

ined. Where the surface cells appeared to be thicker, additional weights were added to give a load of approximately 10 lb.

The first casts made were of barbs without barbules; but later it was found that the presence of barbules made very little difference to the casts. Barbs from the feathers of Guinea fowl, 'Silky' fowl and *Chlorophanes spiza* (Cœrebidæ) were examined in this way. The patterns formed by all these show a network of polygons arranged with their long axes parallel to the length of the barb. Thus the surface cells are of a different shape from those within the cortex, which are long and similar in shape to the cortical cells in mammalian hair.

In some instances, for example, the reverse side of the barb of the Guinea fowl, the following details can be seen in the cast: (1) an oval area corresponding to the original position of the nucleus in each cell; (2) coarse striations; and (3) fibrillary structures. The close moulding of the thin 'surface cells' to the cortex proper may be the reason why the coarse fibrillary striations, arranged in parallel in the cortex proper, are visible in the cast. The patterns formed by the fibrillary structures within the surface cells are not always clearly visible in the casts of all feather barbs; but in the cast of the reverse surface of the barb of Guinea fowl the pattern formed by these structures can be seen superimposed upon that formed by the parallel fibrillary striations of the cortex proper. This pattern gives the effect of a delicate cross-hatching with a distinctly longitudinal trend within the network formed by the boundaries of the surface cells (see photograph).

Further evidence of cell boundaries is seen in transverse sections of the feather barb of the Guinea fowl. Indentations can be seen in the surface margin of the reverse side of the barb when thin (one micron) unstained sections are viewed by phase-contrast using 1/12 in. oil-immersion objective.

Sedimentation in the Tropical Indian Ocean

As a result of recent investigations[1] into the distribution of the Radiolaria in the sediments collected by the Swedish Deep-Sea Expedition in the Western Pacific Ocean, two conclusions of outstanding importance can be drawn: first, that several species of Radiolaria which are widely distributed in the tropical oceans of the present day do not extend farther back in time than the very latest Tertiary or early Quaternary; secondly, that erosion and re-distribution of older sediments on the deep-sea floor often result in the mixing of the tests of Tertiary Radiolaria with Recent ones in that region.

With the object of determining whether either of these effects could be found in the sediment cores collected by the Expedition in the tropical Indian Ocean, a preliminary examination was made of the Radiolaria from samples taken at 1-metre intervals in the following cores:

Core No.	Position		Depth
	Lat.	Long.	
125	S. 10° 07′	E. 106° 56′	6,875 m.
127	S. 11° 07′	E. 103° 39′	5,650 m.
128	S. 11° 28′	E. 102° 24′	5,170 m.
137	N. 01° 56′	E. 88° 12′	4,300 m.
141	N. 02° 18′	E. 76° 02′	3,765 m.
142	N. 00° 35′	E. 75° 14′	4,050 m.
143	S. 00° 31′	E. 74° 33′	3,314 m.
145	S. 01° 20′	E. 68° 20′	3,620 m.
147	S. 01° 19′	E. 66° 16′	4,380 m.
149	S. 01° 22′	E. 62° 38′	4.760 m.
154	S. 00° 23′	E. 54° 30′	4,860 m.
155	N. 04° 28′	E. 52° 48′	5,117 m.

This examination showed that all the characteristic present-day tropical species occurred in all cores at all levels—even those species which are known to have short time-ranges do not disappear at the bottoms of the cores. No Tertiary Radiolaria were found in any of the samples examined.

From these results it can be concluded that, along the course of the Swedish Deep-Sea Expedition in the Indian Ocean, there is no locality where Tertiary sediments have been laid bare by bottom currents which have eroded them and re-distributed their components. This is in strong contrast to the results from the Western Pacific Ocean, where such effects of current erosion seem to be widespread.

The reason for this difference in the results from the two oceans probably lies in their different geological histories. The floor of the Indian Ocean has been a region of comparative tectonic quiet since the Eocene. Thus there have been no major changes in the topography of the sea-floor which would result in widespread re-distribution of sediments. The Western Pacific, on the other hand, was a region of considerable diastrophic activity at the close of the Tertiary, and therefore late Tertiary sediments in that area must often have been brought into the sphere of action of bottom currents.

Even though there is no evidence of recent erosion of Tertiary sediments in the tropical Indian Ocean, it is not impossible that Quaternary sediments are being moved, to a certain extent, by bottom currents. Nevertheless, the magnitude of this process must be much less than in the Western Pacific.

For the facilities for carrying out this investigation, I am indebted to Dr. B. Kullenberg, of this Institute.

Cone Electroretinography by Flicker

It is generally assumed that the *b*-wave of the human retinal action potential is due to the stimulation of the rods. With an intensity of 2,000 lux, the *b*-waves fuse at a frequency of about 20 flashes per second. At lower intensities the fusion frequency in our experiments decreased. A linear relation was found between fusion frequency and the logarithm of stimulus intensity. However, the subjective fusion frequency, determined by cone activity, is known to reach values around 50–60 flashes per second. These high values are never obtained with the *b*-waves of the electroretinogram as index. This is but one of several reasons for assuming the *b*-waves to express rod activity.

According to Karpe and Tansley[1], the threshold of the scotopic *b*-wave of the electroretinogram is higher than the sensory threshold. In agreement with expectations from the general theory of the electroretinogram[2], Adrian[3] found the photopic electroretinogram to be characterized by larger initial negative *a*-waves. It was therefore held that flicker at very high light-intensity might give evidence for cone activity by changing into (negative) *a*-wave flicker from the low-frequency (positive) *b*-wave flicker. This proved to be the case. When we increased the light-intensity until the *b*-waves were preceded by well-developed *a*-waves, the *b*-waves decreased (Figs. *A*–*C*) and the *a*-waves increased (*B*–*C*) as flicker frequency rose (see legend of diagram). The *b*-waves disappeared at a flash frequency of about 20 per sec. The negative *a*-waves appeared to have maximum amplitude at about 25–35 flashes per sec. It seems very likely that their quick return after each flash is due to a true off-effect. This off-effect becomes more pronounced if the *PII* component of Granit's analysis has been removed. Onset of fusion of fast flicker was accompanied by decrease of amplitude. It depended upon stimulus intensity in the same way as the *b*-flicker at lower intensities. Fusion coincided with sensory fusion. The highest fusion frequency observed was at about 55 flashes per second. A reduction of light-intensity to one-tenth reduced the fusion frequency to 35.

From the results obtained by Granit[2], it appears likely that the decrease of the subnormal *b*-waves with increasing frequency of stimulation by intermittent light is caused by an accumulation or increase of post-excitatory inhibition. The amplitude of the rapid potential changes, *a*-wave and off-effect, goes on increasing even after the fusion frequency of the rods has been exceeded. Actually the human retina, which to the ordinary range of stimulus intensities behaves like an *E*-retina, turns into an *I*-retina at higher intensities. Similar transitions are known for other eyes (for example, frog[2]), and the suppression of the *I*-properties at lower intensities has been ascribed to a general inhibition exerted by the rods on the cones.

Enroth[4] has recently shown that the limiting conditions for fusion in individual retinal elements of the cat's eye can be strictly determined. Fusion in, for example, an off-response results if the difference between the latencies of the off-response and the pre-excitatory inhibition is equal to the length of half a flicker period. We assume that the fusion of the rapid potentials in the human retina follows a similar pattern.

These observations are of some general interest because they seem to offer means of studying objectively the photopic function of the human retina.

Flicker electroretinogram at different intensities and frequencies of stimulation. The numbers in each row give the frequencies. Upper row, (*A*): intensity approximately 2,000 lux. Fusion of the sub-normal *b*-waves occurs at 18 stimuli per second. Middle row, (*B*): intensity approximately 2,000 lux; the *b*-waves are preceded by negative *a*-waves, the amplitude of which increases with increasing frequency. Simultaneously the *b*-waves decrease in amplitude. Fusion frequency is 36 stimuli per second. Lower row, (*C*): intensity approximately 24,000 lux. After passing the fusion frequency of the *b*-waves, the *a*-potentials display a further increase in amplitude the maximum of which is reached at about 25–35 stimuli per second. Fusion at 53 stimuli per second. Calibration, upper left-hand corner, 0·1 mV.; time marker, 1/10 sec.

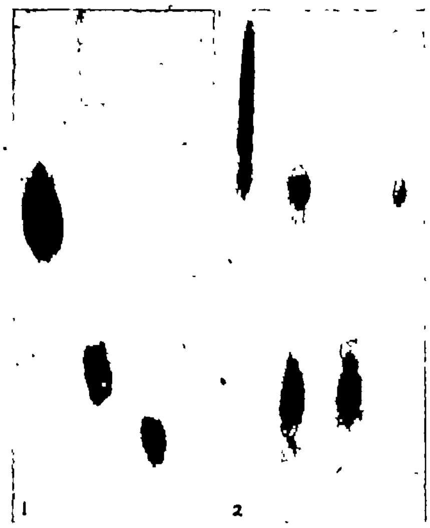
Paper Chromatography of the Pyrogallol Tannins

By one-dimensional paper partition chromatography, some of the phenolic substances allied to the pyrogallol tannins have been separated. When using the well-known solvent phases such as butanol/acetic acid and phenol, previous workers[1] have found that the simpler phenols tend to give long diffuse trails. The preparation of the more complex phenols, such as are found among the pyrogallol tannins, is complicated by their ready oxidation in the presence of bases. Tailing of the spots in neutral and acidic solvents is influenced by the acidity of the mobile phase (cf. organic acids[2]). Addition of strong organic acid to the eluting solvent causes separation into well-defined spots. Unfortunately, formic acid greatly increases the rate of run of the tannin, the spots coming too close to the solvent front for clear definition. Two new solvents have now been found which separate many mixtures of complex phenols into well-defined spots : (1) phenol/acetic acid/water, prepared by adding 30 ml. glacial acetic acid to approximately 500 ml. liquid phenol and just saturating



(1) Phenol/trichloracetic acid/water. Left to right: digalloyl glucose, gallic acid, split acid.

(2) Phenol/acetic acid/water. Left to right: gallotannic acid, synthetic pentagalloyl glucose, synthetic pentagalloyl glucose after passage through column of 'Amberlite *IR4b*', gallic acid

with water at room temperature; (2) phenol-trichloracetic acid/water, prepared by adding 35 gm. trichloracetic acid to approximately 500 ml. liquid phenol and just saturating with water at room temperature.

Spots containing approximately 20 μgm. of each substance are eluted down Whatman No. 4 paper and the chromatograms are dried thoroughly and sprayed with ammoniacal silver nitrate solution (0·1 *N*), when the separate substances appear as black spots in the cold. The R_F values of the different tannins vary considerably with temperature, and for identification purposes it is more reliable to run control spots than to use the mathematical technique.

Employing this method, it has been possible to separate widely different types of compounds, such as chebulinic acid[3] and its hydrolysis products, digalloyl glucose, split acid and gallic acid (Fig. 1). The method has been used to check the purity of synthetic and naturally-occurring amorphous pyrogallol tannins. Thus synthetic amorphous pentagalloyl glucose, prepared via the acetyl derivative, contains at least four compounds (Fig. 2) and is not, as assumed, a single substance. Similarly gallotannic acid, when free from gallic acid, contains more than one compound, none of which is present in impure synthetic pentagalloyl glucose. Hydrolysis of gallotannic acid and similar complex materials by acid, or water in sealed tubes at 100° C., gives pyrogallol as well as gallic acid, indicating that some decomposition occurs.

The pyrogallol tannins of *Terminalia chebula* (Myrobalans) have been separated using the two solvents. A more detailed account of this work will be reported later.

Paper Partition Chromatography of Some Organic Bases by the Method of N-Methylation

The precipitate formed between organic basic substances and Dragendorff's reagent is influenced by the valency of the basic nitrogen atom and by hydrophilic groups, such as carboxyl, hydroxyl, etc.[1]. Difficulties in the use of this reagent can often be overcome by a preliminary N-methylation.

The procedure recommended is as follows. Place a small quantity of an aqueous or methanolic solution of the basic substance not reacting readily with Dragendorff's reagent, such as ephedrine, the sulpha drugs, marfanil, benzedrine, etc., on a paper strip and develop it for about twenty hours in butanol acidified with acetic acid (butanol : water : acetic acid = 5 : 4 : 1) by the ordinary procedure of paper partition chromatography (ascending method). After drying, a 10 per cent aqueous solution of potassium carbonate is sprayed on the paper strip and the drying repeated. The paper strip is then immersed in dimethyl sulphate, pressed between layers of filter papers using a rubber roller in order to remove excess reagent, and warmed to 90° for ten minutes in an air bath to complete the N-methylation process.

On spraying with Dragendorff's reagent (diluted five times with 70 per cent acetic acid), a red or reddish-orange colour is revealed at the positions occupied by the basic substances with quaternary nitrogen atoms. The method is also applicable to the extracts of crude drugs.

Examples of R_F values of basic substances obtained by this method are as follows:

(±)-Ephedrine hydrochloride	0·78	Nicotinic acid	0·75
(−)-Ephedrine hydrochloride	0·82	Pyridoxine	0·61
(+)-Ephedrine hydrochloride	0·79	Sulphapyridine	0·82
Marfanil	0·43	Theobromine	0·56

Detection of Enzymes by the Agar-Plate Method and its Application to Paper Chromatography

In a communication under the above title, Giri[1] describes the use of a starch agar gel for the location of amylases on the paper chromatogram. The technique seems to be essentially the same as that used in this Department, and previously described in *Nature*[2].

The following comments may be made on the technique. Giri[1] obtains marked movement of certain amylases with 50 per cent acetone, whereas, in this laboratory, 50 per cent acetone produces little, although 40 and 30 per cent acetone show marked movement; this may be due to the higher ambient room temperature in Giri's experiments. Most enzymes examined show a marked tailing effect even with low concentrations, which is not apparent unless the time of incubation on the gel is prolonged (18–24 hr.). With the exception of polygalacturonase and pectin-esterase, it has not been possible to separate enzymes, as each is resolved into two or more components and the components from different enzymes frequently overlap. The exact status of these components is as yet undetermined; for example, the number of components and the resulting pattern of the gel-developed chromatogram vary with amylases from different sources. In general, solvent – water mixtures are preferable to aqueous salt solutions as developing agents.

Mitchell, Gordon and Haskins[3] found that both adenosine-deaminase and amylase could be resolved into components on a pile of filter paper disks with ammonium sulphate solutions as developing agents.

It is probable that the chromatographic technique is comparable to electrophoresis in that it separates enzyme proteins due to differences in physical properties rather than differences in enzymic behaviour, for example, kinetics. The R_F-value has been of little use in this technique, as it is markedly affected by slight changes in the conditions of development.

Full experimental details are being submitted for publication elsewhere.

Chromatographic Evidence for the Tetraphosphate Ion

A KNOWLEDGE of the structure of phosphorus pentoxide, P_4O_{10}, enables predictions to be made concerning the mechanism of its hydration to orthophosphoric acid and particularly about the structures of the phosphoric acids formed intermediately[1]. In order of their formation, these would be expected to be $H_2P_4O_{11}$, $H_4P_4O_{12}$ (tetrametaphosphoric acid), $H_6P_4O_{13}$ (tetraphosphoric acid) and eventually mixtures of $H_5P_3O_{10}$, $H_4P_2O_7$ and H_3PO_4. Salts of tetrametaphosphoric acid have already been isolated and identified by X-ray and other methods from the alkaline hydrolysate of P_4O_{10}, and we have explored the use of paper chromatography as a means of separating the tetraphosphate ion. Aqueous solutions which would be expected to contain the latter were made by controlled alkaline hydrolysis of sodium tetrametaphosphate, using conditions analogous to those giving sodium triphosphate from sodium trimetaphosphate and similar to those described by Thilo and Rätz[2].

Chromatographic evidence for the existence of the tetraphosphate ion was obtained at Cambridge by one of the authors in association with Dr. C. S. Hanes using the techniques developed by Hanes and Isherwood[3] in their study of phosphoric esters. This chromatic evidence has been confirmed in detail by further work at Toronto.

In both laboratories the sodium tetrametaphosphate hydrolysate was prepared by heating 1 gm. of the tetrahydrate for 2 hr. at 70° C. with just sufficient alkali to break the ring. This was chromatographed alongside pure specimens of the orthophosphate, pyrophosphate, triphosphate, trimetaphosphate and tetrametaphosphate kindly supplied by Dr. B. Raistrick.

A number of solvent mixtures were used, of which *n*-propanol, water, 0·88 sp. gr. ammonium hydroxide (60, 20, 20 by volume respectively) is a good example. A strong spot which by colorimetric analysis accounted for 60 per cent of the hydrolysate appeared in a position where the tetraphosphate ion might logically be expected, and could not be ascribed to any of the other anions conceivably present.

During the course of this work, it was noted that a separation of orthophosphate, pyrophosphate and triphosphate anions could be obtained. Furthermore, it was observed that a sample of commercial sodium triphosphate, which by usual methods of analysis had a pyrophosphate content of 3–10 per cent, gave on chromatographic analysis two spots, the fainter one occupying the pyrophosphate position. It would seem, therefore, that a chromatographic separation of the phosphate anions should lead to an improved method for their quantitative analysis.

Vapour Pressure of Isotopic Carbon Tetrachlorides

A THEORY of the vapour pressure relationship for isotopic molecules has been given by Topley and Eyring[1]. It is, however, difficult to see *a priori* how to apply the theory in calculating vapour pressures for a particular case, in view of our lack of knowledge of the liquid state. The isotopic molecules of carbon tetrachloride would be expected to be very favourable cases for showing differences of vapour pressures if they exist. Grimm[2] carried out a multiple fractionation with a single small packed column and calculated that neighbouring isotopic molecules on the mass scale had boiling points not differing by more than 0·001° C. We have calculated from Grimm's results that his total fractionation was equivalent to 75 theoretical plates.

Modern packed columns have much higher efficiency and can be operated automatically. We have made use of three packed columns constructed by Dr. Newell Cook of the Chemistry Department of this College in an attempt to fractionate the isotopic molecules of carbon tetrachloride.

These columns have probable theoretical plate ratings of 100, 200 and 400 plates respectively, and are completely automatic in operation. We have operated the columns in such a manner that the first distillate was charged into the second column, etc. The reflux ratio used was 1,000 : 1. The last column was brought to equilibrium, and the specific gravity of the equilibrium mixture relative to the original charge of the first column determined. Since the first column was continued in operation after it had furnished its charge to the second column, a cut was taken near the end of the distillation and this sample compared with the top of the third column.

The specific gravity was determined by the buoyancy balance method described by Lewis and MacDonald[3], which had a sensitivity at least as great as 1·8 in the fifth decimal place. We were not able to detect the slightest difference in the density of the various samples.

Carbon tetrachloride is particularly favourable for such a fractionation experiment, since one can be sure of its purity to a degree unable to affect the density to the above precision by examining the infra-red spectrum in a liquid cell 1 cm. or greater in thickness.

Since the experiment gave completely negative results, it is only possible to calculate the maximum possible difference in the vapour pressures from the sensitivity of the apparatus. If we make a few reasonable assumptions, this is easily accomplished.

If A is the fractional part of chlorine of mass 35 and B the fractional part of chlorine-37, that is, $A + B = 1$, statistically the population of the five types of isotopic molecules will be given by the expansion of $(A + B)^4$. Each term of this expansion is identically equal to the mole fraction M_i of the particular molecule A_nB_m, where n and m represent the number of chlorine atoms of the mass in question.

We shall assume that the difference in vapour pressures of progressively heavier isotopic molecules varies linearly with increased mass. We shall make a further but somewhat doubtful assumption to simplify the calculations, that free statistical exchange of isotopic chlorine atoms is possible. This assumption in any event will not greatly affect the result. We can now write the following relationships:

$$M_1 + M_2 + M_3 + M_4 + M_5 = 1; \qquad (1)$$

$$M_1^* + M_2^* + M_3^* + M_4^* + M_5^* = 1; \qquad (2)$$

where the M's refer to the mole fractions of the various isotopic molecules and * quantities refer to enriched samples. If p is the vapour pressure of the most volatile molecule, namely, $C^{35}Cl_4$, the relative volatilities will be

$$1, \frac{p-\delta}{p}, \frac{p-2\delta}{p}, \frac{p-3\delta}{p}, \frac{p-4\delta}{p}. \qquad (3)$$

δ is obviously the difference in vapour pressure between neighbouring isotopic molecules on the mass scale. The composition of the distillate will be given by:

$$M_1 + M_2\left[\frac{p-\delta}{p}\right]^n + M_3\left[\frac{p-2\delta}{p}\right]^n + M_4\left[\frac{p-3\delta}{p}\right]^n + M_5\left[\frac{p-4\delta}{p}\right]^n = S, \qquad (4)$$

where

$$M_1^* = \frac{M_1}{S}, \; M_2^* = \frac{M_2}{S}\left[\frac{p-\delta}{p}\right]^n, \ldots \; M_5^* = \frac{M_5}{S}\left[\frac{p-4\delta}{p}\right]^n,$$

and n is the number of theoretical plates.

From the minimum detectable density change, it is possible to calculate the minimum detectable change of molecular weight, and thus to calculate the quantities M_1^* from the new values for A^* and B^* inserted into $(A^* + B^*)^4$. Solution of equation (4) is now easily possible and yields a value of δ of $1\cdot4 \times 10^{-3}$ mm. of mercury for a value of n of 700 theoretical plates and a change of specific gravity of 1·8 in the fifth decimal place.

From this result it follows that neighbouring isotopic molecules do not differ in boiling point by more than 6×10^{-5} degrees centigrade. It is conceivable that the vapour pressure differences of these isotopic molecules could be greater than we have calculated. Cohen[4] has shown that when fractionation processes are carried out with materials of very close boiling points, the equilibrium times become extremely long and minor disturbances have a large effect on the efficiency of the column. The net effect is, of course, a marked reduction of the effective number of plates in the column.

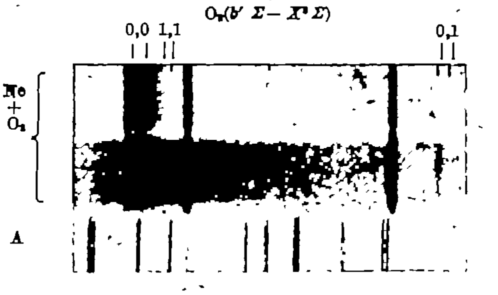
Atmospheric Oxygen Bands in Emission from Neon–Oxygen Mixtures, and in Night Sky and Auroral Luminescences

IN a recent paper, Meinel[1] suggested that the radiations at 8628 A. and 8659 A. in the night sky luminescence might be identified as the R and P branches of the (0,1) band of the atmospheric oxygen system, $b^1\Sigma^+_g - X^3\Sigma^-_g$. Other bands of this system might also be present, and the absence of the most intense band, the (0,0) band, was accounted for by the reabsorption in the lower atmosphere.

This oxygen band system, best studied in absorption, has in the past few years been observed in emission by several investigators[2-4]. In spite of this, wave-length data of band heads and approximate origins are somewhat scarce and relative intensities are not given at all. More information about them is therefore needed.

In the emission from discharges through pure oxygen and neon–oxygen mixtures, I have observed three bands of the system. The (0,0) band at 7592·5, 7622·5 A. (R head and approximate beginning of the P branch, as measured from my plates) was by far the most intense. Exposure times of less than 5 sec. were sufficient to produce a suitable photographic density of the band (on unsensitized Eastman *I N* plates with a *B* II spectrograph from the Société Générale d'Optique). The two other bands observed were the (1,1) band at 7680 (partly masked), 7710·5 A. and the (0,1) band at 8604·2, 8649·8 A. with intensities of about 0·5 and 2 per cent respectively of that of the (0,0) band.

The discharges were successfully run both by ordinary high tension (50 c./s.) between cold electrodes in the discharge tube and by high-frequency tension (2 Mc./s.) between external electrodes. (In the latter case the emission had a silver-white appearance due to a strong and very even continuum extending throughout the whole region investigated, 3200–



0·02 per cent oxygen in neon. Total pressure, 700 mm. mercury. High-frequency excitation

9700 A.) Variation of total pressure and oxygen concentration did not appreciably influence the relative intensities of the bands, whereas the absolute intensities varied considerably.

This variability of the band intensities gives some information on the collision deactivation probability of the metastable $O_2(b^1\Sigma)$ state. A method similar to that used in the investigation of the metastable $O\,I(^1S)$ state[5] was adopted. Preliminary results seem to indicate that the sensitivity against non-radiative deactivation of the lowest two vibrational levels in the $O_2(b^1\Sigma)$ state is slightly less than that of the $O\,I(^1S)$ state.

The mean life-times of the molecular[6] and atomic metastable states here mentioned are of the same order of magnitude. The collision-deactivation of the two states under similar conditions should therefore, according to the preliminary result, also be of about equal magnitude. Bearing in mind that in the upper-atmosphere oxygen atoms, excited to the $2s^2 2p^4$ ^1S state, are left undisturbed long enough to be deactivated by radiation, there is reason to believe that this should also apply to the $O_2(b^1\Sigma)$ state, provided oxygen molecules exist there. Evidence of this, however, has recently been supplied by the discovery of O_2^+ bands in the auroral spectrum[7]. Meinel's identification of atmospheric oxygen bands in the night sky luminescence seems, therefore, highly probable.

The similar behaviour of the two metastable states also indicates that the atmospheric oxygen bands might be present in the auroral spectrum with appreciable intensity. There is some experimental evidence in favour of this. On the infra-red auroral spectrogram obtained by Meinel[8], an unidentified radiation with short wave-length limit just above 8600 A. fits very well with the *R* head of the (0,1) band. The *P* branch is partly overlapped by the N_2 1*P*(2,1). The sharp short wave-length side of the N_2 1*P*(2,0) band may be due to overlapping of the *R* branch of the molecular oxygen atmospheric (1,1) band. But here the absorption of the (0,0) band of the same system sets in, which may result in a similar effect.

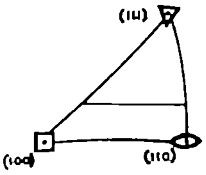
Effect of Orientation on the Metallic Reflexion of Polarized Light

E. C. W. Perryman and Miss J. M. Lack[1] have attributed the optical anisotropy of etched monel, which is face-centred cubic and should be optically isotropic, to the presence of a surface structure. They find, however, that optically anisotropic cadmium does not possess a similar structure.

By studying the reflexion of polarized light under crossed nicols from grains of known orientation, we have obtained information concerning the nature of three different types of anisotropic reflexion. These are exemplified by reflexions from surfaces of etched monel metal, isotropic aluminium the surface of which has been etched to develop cubic etch pits, and unetched anisotropic beryllium. A Bausch and Lomb elliptical vibration compensator[2] was used under a rotating stage to measure the change of phase and the rotation of the reflected polarized light.

It is well known that plane-polarized light is not affected by reflexion from an inclined polished plane if the plane of vibration is parallel or perpendicular to the axis of tilt. If these conditions are not met, the reflected light is no longer plane-polarized and can be observed under crossed nicols. Thus, when a scratch is parallel or at right angles to the plane of vibration, the scratch extinguishes the light. At intermediate positions, the scratch appears bright. The inclined faces of cubic etch pits on the surface of aluminium furnish a means of studying this 'scratch effect'. When the three sides of the pits are approximately parallel and perpendicular to the plane of vibration of the incident light, the grain will show extinction. This has been experimentally verified for all orientations below the solid line of the diagram. However, since the etch pits are not all true planar surfaces, the amount of rotation and phase change created is not constant and cannot be determined experimentally.



Large-grain aluminium specimens were etched to develop cubic etch pits. Those with orientations below the solid line showed extinction when the plane of the cube pole closest to the horizontal agreed with or was perpendicular to the plane of vibration of the light

Grain growth studies of monel[3] have shown that a crystallographically straight interface, or the straight part of a jagged interface, is evidence of the presence of a spinel twin relationship. When traces of the four {111} planes of a grain have been plotted, the orientation can be uniquely determined. By this means, the orientations of most of the grains in several fields (× 250) were determined. By repolishing and re-etching, it was found that whereas the maximum intensity from an individual orientation might vary, the position of extinction with respect to the plane of vibration of the light remained the same, that is, extinction was reproducible.

A study of the interference figure and a correlation of the orientation with measurable rotations and phase changes[4] indicated that the anisotropy was due to the presence of a uniaxial crystal on the surface of the metal, the c-axis and therefore the extinction position of which always lay within 1·5° of the plane containing a cube pole of the monel. The inclination of the c-axis to the specimen surface within this plane was also that of the cube pole, that is, minimum intensity of reflexion when the c-axis is vertical and maximum when it is horizontal. By polishing electrolytically, and using the etching solution as the electrolyte, the thickness of this film, as well as the measurable rotation and phase change, can be increased appreciably without removing the orientation relationship. A chemical spot test showed the increased presence of a chromate. The anisotropy of etched monel is therefore attributed to a layer of hexagonal copper chromate. We feel that the fact that the minute etch pits and troughs, observed on the surface of monel by Perryman and Lack, can be compensated for as to phase change and rotation, must mean that their faces are crystallographically quite planar.

Single-grain specimens of hexagonal beryllium, which is optically active after mechanical or electrolytic polishing, show a reproducibility of extinction position[3]. In this case, there is extinction within a range of ± 2° when the intersection of the basal plane with the surface of the specimen is parallel or perpendicular to the plane of vibration of the incident light, regardless of the method of polishing. As the specimen is rotated through 360° from the extinction position, two symmetrical sets of unequal peaks are observed. The intensities of any two successive peaks are at a maximum when the basal plane is perpendicular to the surface, and a minimum when it is parallel. The graph of the measured angle of rotation of the plane of polarization versus the angle of inclination of the basal plane is linear and when extrapolated becomes 0 at 0° inclination; that is, there is no rotation when the basal plane is parallel to the surface.

The measurable anisotropy varies with temperature and on exposure to oxygen. This effect is attributed to the time-dependent development of a 'chemi-sorbed' layer at the beryllium – beryllium oxide interface[4].

Metallographically, it is of interest to note that the extinction position, in all cases studied, is reproducible and bears a definite relationship to the orientation of the grain under observation. When several orientations are prepared in a similar manner, as in a polycrystalline aggregate, the relative maximum intensities of the grains are a function of the orientation.

This work was carried out at the M.I.T. Metallurgical Project under Contract No. AT—(30–1)—981 with the U.S. Atomic Energy Commission and the U.S. National Bureau of Standards.

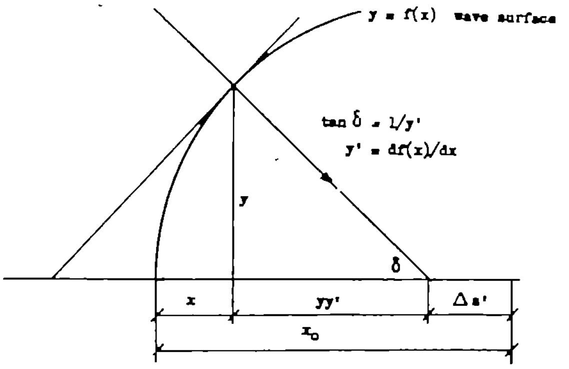
A Formula for determining the Wave-Surface if the Spherical Aberrations are Known

If the spherical aberrations of a cylindrical symmetrical optical system are known in the form of a series:

$$\Delta S' = a \tan^2\delta + b \tan^4\delta + c \tan^6\delta + \ldots, \quad (1)$$

it is possible to deduce the equation of the orthotomic wave-surfaces to the rays defined by (1), as has been shown by Picht[1]. Picht gives a recursion formula proceeding from the higher terms to the lower, which is very inconvenient if the constants $a, b, c, \ldots$ increase rapidly, as is ordinarily the case. It is possible, however, to obtain a recursion formula proceeding from the lower terms to the higher, which has been found very useful for practical purposes while analysing the concentration of light near the geometrical focus[2] by the Debye–Picht method.



From the accompanying diagram we obtain the relation

$$x_0 = x + yy' + \Delta S', \quad (2)$$

which gives the differential equation of the wave surfaces:

$$yy' + \frac{a}{y'^{2}} + \frac{b}{y'^{4}} + \frac{c}{y'^{6}} + \ldots x - x_0 = 0. \quad (3)$$

This can easily be solved by a Legendre transformation, and by introducing the unknown variable in the transformed equation in the form of a series of the powers of the parameter $\tan^2\delta$ and determining the constants by putting the sum of them for each power equal to zero. In this way we get the meridional co-ordinates of the wave surfaces:

$$x = -A \tan^2\delta - 3B \tan^4\delta - 5C \tan^6\delta \ldots \quad (4)$$

$$y = -2A \tan\delta - 4B \tan^3\delta - 6C \tan^5\delta \ldots \quad (5)$$

with the recursion for the constants:

$$A = -\frac{x_0}{2};\ B = \frac{a-A}{4};\ C = \frac{b-3B}{6};\ D = \frac{c-5C}{8}. \quad (6)$$

Compressibilities of Cubic Crystalline Powders: a New Method of Measurement

By suitable averaging, the following relations may be derived for polycrystalline aggregates consisting of randomly oriented and ideally closely packed particles of any substance crystallizing in the cubic system:

$$C'_{11} = \frac{3}{5}C_{11} + \frac{2}{5}(C_{12} + 2C_{44});$$

$$C'_{44} = \frac{3}{5}C_{44} + \frac{1}{5}(C_{11} - C_{12}).$$

C'_{11} and C'_{44} are the thickness and shear elastic constants of a plate of the aggregate and C_{11}, C_{12} and C_{44} are the elastic constants of the corresponding single crystal. If the crystal is such that the Cauchy relation $C_{12} = C_{44}$ holds good, the above equations become dependent on one another and reduce to $C'_{11} = 3C'_{44} = \frac{3}{5}(C_{11} + 2C_{12})$. If $C_{12} \neq C_{44}$, they remain independent but may be combined to give $3C'_{11} - 4C'_{44} = C_{11} + 2C_{12}$. Thus, the measurement of C'_{11} and C'_{44} will enable us not only to state whether the Cauchy relation holds good for the crystal under investigation, but also to evaluate the bulk modulus K, which is $\frac{1}{3}(C_{11} + 2C_{12})$.

C'_{11} and C'_{44} can be conveniently measured by the ultrasonic wedge method, developed and described by us in earlier publications[1]. Results obtained for a few test cases, using cubic crystal powders, compressed into plates of suitable dimensions, are given in the accompanying table in units of 10^{11} dynes per cm.^{2}.

Substance	C'_{11}	C'_{44}	$K = \frac{5}{9}C'_{11}$	K (direct measurement)
KCl	3·16	1·07	1·76	1·77
KBr	2·71	0·91	1·51	1·50
KI	2·19	0·76	1·22	1·17
NaCl	4·37	1·47	2·43	2·40

C'_{11} in all cases is three times C'_{44}. This is in conformity with the known fact that the Cauchy relation holds in all these crystals. Moreover, K obtained from C'_{11} (column 4) agrees well with the value available in the literature for each case (column 5).

It is proposed to extend this method to as many aggregates as possible, and the results will be published elsewhere.

Reaction between Glucose and the Terminal Amino Group of Lysine

Patton and Chism[1] have recently used paper chromatography followed by examination of the unheated papers under an ultra-violet lamp for demonstrating a series of fluorescent products in boiled glucose–glycine solutions. We have been using a similar technique in an investigation of the reaction between glucose and α-N-acetyl-L-lysine at 37° C. and have found it particularly effective when combined with a study of the effect of water content on the course of the reaction.

Freeze-dried mixtures of the two substances (1½ moles glucose/amino group, *p*H on re-solution 6·5) were shown to react with progressively increasing complexity as the relative humidity increased, until at about 60 per cent relative humidity all the changes characteristic of the Maillard reaction in true solution[2] were occurring. The reaction products were examined by descending paper chromatography with 80 per cent aqueous propanol as solvent.

At 20 per cent relative humidity a simple one-to-one glucose–amino combination took place and gave rise to a spot at R_F 0·1 (*A*) which had all the properties described by Gottschalk and Partridge[3]. Glucose and α-N-acetyl-L-lysine were clearly separated at R_F 0·3 and 0·2. At 30 per cent relative humidity there appeared, in a characteristic band on the rear edge of the first spot, a second compound (*B*) which gave a bright purple fluorescence under an ultra-violet lamp and on elution showed a pronounced absorption peak at 2880 A. Reduction of ammoniacal silver nitrate and ferricyanide at *p*H 5 occurred in the area *AB*. At 40 per cent relative humidity a series of non-reducing pale-blue-fluorescent compounds (*C*) appeared at R_F's 0·05, 0·03 and 0·01, while brown products (*D*), which had now begun to accompany the reaction, remained stationary. Compounds *C* and *D* could be reproduced by storing the isolated amino–glucose complex *A* at 40 per cent relative humidity, and this, combined with a progressive movement towards the visible region of a poorly defined peak in their absorption spectra (reaching 3280 A. in the brown compounds), suggests that they are successive degradation products of the complex.

At 60 per cent relative humidity the pattern of the fluorescent compounds, though similar, was more complex and has not yet been examined in detail. It is interesting to note, however, that several of the complex effects, including browning, fall in *p*H and loss of glucose in excess of the one-to-one relationship, reached a maximum at this humidity, whereas the maximum rate of loss of amino groups occurs at 40 per cent relative humidity. A similar behaviour has already been observed in the protein–sugar reaction[4].

The precise chemical nature of compounds *A* and *B* still remains to be determined. Both appear to be primary products of a one-to-one reaction, but neither liberates glucose on acid hydrolysis nor undergoes reduction by hydrogen and palladium black at room temperature and pressure. There is therefore as yet no direct evidence for an N-glycoside or *iso*glucosamine structure of the type well known in the aromatic series. Compound *A* appears to be one of the main intermediaries in the browning sequence; but sufficient browning to account for that of the intact systems could only be achieved by storage of *A* with all the slower-moving compounds (except *D*). This mixture browned two or three times as rapidly as *A* alone. At least one of these other compounds is therefore also involved, possibly in a catalytic role, since only *A* browns when a developed paper chromatogram is heated.

These experiments, and others with a preparation of polylysine of molecular weight 10–15,000, were carried out with the object of assessing the extent of the contribution of the terminal amino groups of lysine to the effects already observed with intact proteins[4,5]. Similar effects were observed in all three systems[6], confirming the view that the free amino groups of the protein are of great importance in the protein – sugar reaction. Even insolubility, preceded by an increase of molecular weight, occurred in the polylysine experiments, showing that cross-linking can apparently occur without the participation of other amino-acid residues.

This work was carried out as part of the programme of the Food Investigation Organization of the Department of Scientific and Industrial Research. A full account will be published elsewhere.

Amino-acids of Silk Sericin

The silk thread extruded by the lava of the silk moth of commerce (*Bombyx mori*) consists of two parts: a central core of two filaments of the protein fibre 'fibroin', surrounded and cemented together by a layer of protein material called 'sericin'.

Analyses of the amino-acids of sericin are widely scattered through the literature[1-4], and are in no case claimed to be complete. By the methods of paper-partition chromatography we have examined the amino-acid constitution of sericin, and demonstrated the presence of fifteen amino-acids. Of these, valine had not previously been reported, and the evidence for a number of others, especially lysine, proline, glycine and phenyl alanine, was very slight.

The sericin was divided into three fractions, depending on their solubility in hot water, or in dilute acid or alkali. This separation follows the general lines described by various earlier workers[4-8]. The outer, most soluble fraction, sericin *A*, had a total nitrogen content of 17·2 per cent; paper chromatography of the hydrochloric acid hydrolysate of this fraction showed it to contain the following amino-acids: serine, threonine, glycine and aspartic acid in high concentration; glutamic acid, arginine, alanine, leucine, *iso*leucine, valine and tyrosine in moderate concentration; and lysine and phenyl alanine in relatively low concentration.

The second fraction, sericin *B*, had a nitrogen content of 16·8 per cent. On acid hydrolysis it yielded the amino-acids of sericin *A* in similar proportions, and in addition some tryptophane.

The third, inner layer of sericin, sericin *C*, adjacent to the fibroin, was insoluble in hot water, but could be removed from fibroin by treatment with hot dilute acid or alkali. Its nitrogen content was 16·6 per cent and on hydrolysis it yielded proline in addition to the amino-acids of sericin *B*. This inner layer also contained sulphur, present as inorganic sulphide. No sulphur-containing amino-acids could be detected.

There was some evidence for the presence of traces of a third basic amino-acid residue in each of the three sericin fractions. This was not histidine, for although histidine has been reported as present in sericin by other workers we could not detect it in any of the hydrolysates by the sensitive Pauly reaction[9]. The spot we obtained may have been due to hydroxylysine; but our evidence regarding this amino-acid was by no means conclusive.

The distribution of the amino-acids in sericin is being investigated by Sanger's technique[10] and by other methods.

Preparation of the Specific Purified Antigen of Canine Hepatitis Virus and Antiserum for Serological Studies

The natural history of mammalian hepatitides viruses supports the concept of a widespread unapparent infection[1,2] which makes it extremely difficult to study the problem by experimental inoculations without a reliable serological test. This communication describes a simple method for the purification and concentration (if necessary) of the antigen, as well as the preparation of the active antiserum for serological studies. Four strains of the virus have been used in these experiments: two English strains, one from Australia and one from Sweden.

Preparation of antigen. Methanol cooled to –30° C. was cautiously added to a final concentration of 30 per cent to a cooled fine 10 per cent suspension of a virus-rich tissue in distilled water or to undiluted body fluid (such as serum, peritoneal fluid, etc.), while it was kept in an ice box. The resultant turbid fluid was held at 0° C. for 2–3 hr. and then centrifuged at 4,000 r.p.m. until all the suspended particles were thrown down. The supernatant fluid was removed and the sediment was taken up in a volume of 0·85 per cent saline at pH 6·8–7·0 equal (or less, if desired) to that of the original liquid, and after stirring thoroughly it was allowed to stand for 24 hr. at 0° C. Any undissolved material was then removed by centrifugation and the final water-clear supernatant was used as the antigen. Ethanol or butanol can be used instead of methanol, but the resultant antigens appeared to be less active.

Preparation of antiserum. Dogs were hyperimmunized with a fine 10 per cent suspension (in 0·85 per cent saline) of the virus-rich liver. The intravenous or subcutaneous inoculations of the material used were carried out by giving increasing amounts (1 to 11 ml.) of the suspension over a period of three weeks. In the intraperitoneal method three injections were given (5 ml. each) at weekly intervals.

Complement-fixation test. The test mixtures: serum (or dilution) 0·1 ml., antigen (or dilution) 0·1 ml., and complement dilution 0·5 ml. 0·85 per cent saline was always added to make the total volume 1·5 ml. Each reaction mixture was given primary incubation either in a water-bath at 37° C. for 30 min., or in a refrigerator at 3° C. for 16–18 hr., followed by 1 hr. at room temperature. Then 0·5 ml. of hæmolytic system (5 M.H.D. of hæmolytic amboceptor in a volume of 3 per cent sheep red cells suspended in 0·85 per cent saline) was added. This was followed by a final incubation in a water-bath at 37° C. for 30 min. The amount of hæmolysis was estimated in six grades. Before conducting the main test, complement was always titrated in amounts varying by 0·25 M.H.D.

Ring precipitin test. This was carried out by carefully stratifying 0·04 ml. of the viral antigen on 0·04 ml. of test serum in a small test-tube (3 mm. × 25 mm.). The reaction was allowed to stand 2 hr. at 37° C. Definite ring-like precipitate formed at the junction of the two fluids in positive cases.

Quantitative flocculation test. Dilutions of sera and antigen were prepared separately. Each dilution of test serum was set up in as many test-tubes (0·5 ml. in each) as the number of antigen dilutions required to be tested. Then 0·5 ml. of antigen dilution was added into each tube, thus doubling dilutions of both components. Readings were made after the reaction was allowed to stand 18 hr. at 37° C. A definite turbidity noticeable by the naked eye in the daylight appeared in positive tests.

Some properties of the antigen. It can be derived from various virus-rich dog tissues and body fluids, although the lungs and spleen contain less of the antigenic material. It is stable on storage at + 3° and – 30° C., as well as to heating at 56° C. for 30 min. and 1 hr. The supernatant fluid after high-speed centrifugation at 15,000 r.p.m. is antigenically active. Solubility of the active material in organic solvents (benzene, chloroform, petroleum ether, ethyl ether, amyl and butyl acetate) is negligible. The antigen on being inoculated into dogs can induce the specific and sometimes fatal disease. Precipitins and complement-fixing antibodies can disappear completely from the circulating blood after one year and in some cases even earlier. At the same time these dogs appeared to be actively immune to subsequent challenge with the virus.

I am grateful to Dr. H. P. Chu for his kindness in carrying out the high-speed centrifugation, and to Mr. W. G. Orbell for technical assistance. The details of this work will be published elsewhere.

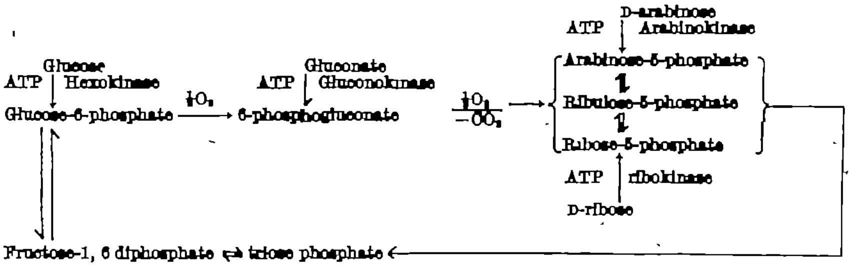
Utilization of Gluconate and Glucose in Growing and Virus-infected *Escherichia coli*

We have described various enzymes in *E. coli* participating in an oxidative pathway of glucose-6-phosphate degradation via 6-phosphogluconate to pentose-5-phosphate and then to triose phosphate. Recently, we have found the specific adaptive transphosphorylases, gluconokinase[1], D-arabinokinase[2], and ribokinase[3] in *E. coli* which permit the insertion of the homologous substrates into this pathway. The Embden–Meyerhof pathway of anaerobic triose formation also exists in these bacteria. These relationships are presented in the accompanying chart.



Alternate pathways for triose phosphate formation

The reaction of glucose-6-phosphate to 6-phosphogluconate has been considered to be essentially irreversible. If this were true, the metabolism of gluconate, for example, could only proceed via the oxidative pathway. To test this, we have measured the liberation of carbon dioxide from the C_1 of gluconate, labelled specifically in that position with carbon-14. *E. coli*, strain *B*, were grown aerobically in Warburg vessels in a mineral medium with gluconate as the sole carbon source. The carbon dioxide was trapped in sodium hydroxide and recovered quantitatively as barium carbonate in the presence of 150 micromoles of diluting sodium carbonate. The radioactivity of the barium carbonate was measured.

During growth on gluconate, the average production of carbon dioxide was 2·3 moles per mole of gluconate. The average recovery of C_1 in carbon dioxide was 88 per cent, recoveries ranging between 84 and 95 per cent. When gluconate was oxidized without growth by pre-adapted bacteria in a 0·05 *M* phosphate buffer at *p*H 7·0, carbon dioxide production was 3·5 moles per mole of gluconate and C_1 recovery was 100 per cent.

Pre-adapted bacteria were infected with about five bacteriophage $T\,2r^{+}$ particles per cell in the presence of labelled gluconate, and C_1 yields were compared with those from uninfected bacteria. Although infected bacteria stopped multiplying, their respiratory quotient and rate of production of carbon dioxide were identical with those of uninfected bacteria. The C_1 recoveries from the two systems were essentially identical and almost quantitative. We conclude from these experiments that the path of gluconate metabolism in growing and virus-infected *E. coli* is almost completely, if not completely, through pentose phosphate, with attendant C_1 liberation as carbon dioxide. Furthermore, the glucose-6-phosphate oxidation to 6-phosphogluconate is essentially irreversible in these bacteria.

The same technique was applied in analysing the routes of glucose utilization by these bacteria. When glucose is converted to triose phosphate via the Embden–Meyerhof scheme, the carboxyl of pyruvate derived from it would contain C_3 or C_4 of the original glucose. Carbon dioxide from this pyruvate might arise from a variety of pathways, two extreme cases being (1) the complete combustion of pyruvate in the tricarboxylic acid cycle, or (2) the preferential liberation of carbon dioxide from the carboxyl. No mechanism is known at present which would give rise preferentially to carbon dioxide from pyruvate —CH_3, which would contain the original C_1 of glucose. In the first case, we would obtain the maximal C_1 liberation as carbon dioxide and the recovery of C_1 in the carbon dioxide would be proportional to the yield of carbon dioxide from glucose.

When C_1-labelled glucose is oxidized by the bacteria in a 0·05 *M* phosphate buffer (*p*H 7·0) free of a nitrogen source, 3·2 moles of carbon dioxide were liberated per mole of glucose. This carbon dioxide contained 54 per cent of the total C_1. Since the specific activity per mgm. carbon of this carbon dioxide was that of the entire glucose, these oxidizing cells gave no indication of a preferential liberation of carbon dioxide from C_1 or of a use of the oxidative pathway.

Under conditions of growth, in which 1·4 moles of carbon dioxide were liberated per mole of glucose, a maximal value of 23 per cent (1·4/6 × 100) could be expected from the combustion of a portion of the pyruvate formed anaerobically. However, an average of 37 per cent (34–39) of the C_1 was recovered in the carbon dioxide in eight experiments. This is significantly in excess of the maximal value of 23 per cent, and the minimal value for glucose degradation by the oxidative pathway would then be 37 — 23, or 14 per cent. The maximal value would be the C_1 recovery or 37 per cent. In either case, the oxidative pathway could be supplying all the ribose requirements of the organism.

C_1 RECOVERY IN CARBON DIOXIDE PRODUCED DURING GLUCOSE UTILIZATION BY *E. coli*

Physiological condition	$\frac{\text{Moles } CO_2}{\text{Mol. glucose}}$	$BaCO_3$ (counts/min./mgm. C)	Recovery of C_1 in CO_2 (per cent)*	Theoretical C_1 recovery (per cent)	Excess (per cent)
Oxidation, no growth	3·22	212	54·4	53·7	0·7
Growth	1·32	156	37·7	22·0	15·7
T2 synthesis	1·38	121	29·1	23·0	6·1

* Calculation after correction for dilution.

When these cells were infected with five bacteriophage $T2r^+$ particles per cell, they stopped growing and proceeded to the synthesis of virus components almost exclusively[3]. Although their respiratory quotient and rate of oxygen consumption were unchanged under conditions of virus infection, the excess of C_1 in the carbon dioxide was markedly decreased. A typical experiment is presented in the accompanying table. This may be interpreted as a shunt in glucose utilization from the oxidative pathway to the anaerobic pathway and occurred under conditions in which ribose nucleic acid synthesis was eliminated and deoxyribose nucleic acid synthesis was stimulated.

We have also observed that gluconate may be used readily for growth, when far more ribose nucleic acid is produced than deoxyribose nucleic acid, but is a poor substrate for virus synthesis when an increased demand for deoxyribose nucleic acid appears. These results suggest that, in glucose utilization by *E. coli*, ribose is derived mainly from the oxidative pathway, and deoxyribose may come from constituents generated most readily from the anaerobic pathway.

This work was supported by a grant from the Commonwealth Fund. I am indebted to Dr. S. Gurin of the University of Pennsylvania for C_1-labelled gluconate, and to Dr. H. S. Isbell of the National Bureau of Standards for C_1-labelled glucose.

Cytology of the Ecotypes of Diœcious *Melandrium dioicum* (L. emend.) Coss. & Germ.

IN 1942, a tetraploid ($2n = 48$) plant of the diœcious *Melandrium dioicum* complex was discovered by D. Löve[1] in a Swedish population. She diagnosed it as "*M. crassifolium* Fries"[2], which Turesson[3] has considered to be a coastal ecotype of *M. dioicum*. From herbarium studies of the morphology of adult plants, she further concluded that "*M. crassifolium*" and *M. rubrum* subsp. *lapponicum* Simm.[4] are synonymous and, as the latter has been regarded by Turesson[3] as forming part of the sub-alpine ecotype of *M. dioicum*, this means that there is no outstanding morphological difference between the 'coastal' and 'sub-alpine' ecotypes of this species. From a comparison of pollen-sizes in her tetraploid and these ecotypes, she concluded that both the coastal and sub-alpine races are tetraploid.

This is important, because it had already been established (in 1940) by Warmke and Blakeslee[5] that a tetraploid race, once formed, could spread without loss of diœcism even though such a race had not then been discovered. Nevertheless, Baker[6–8] has shown that a number of plants representing the coastal ecotype in the Shetland Isles are diploid ($2n = 24$) without any tetraploids being found, despite the fact that this race shows many morphological features normally associated with polyploidy (and even found in artificial polyploids in this genus[5,9]), such as increased flower-, capsule- and seed-size along with thicker and hairier leaves and stems. It was pointed out[6,8] that further evidence that all coastal and sub-alpine plants are not tetraploid had been provided by the determination of diploidy in sub-alpine material collected by Dr. J. Clausen at Abisko (in Swedish Lappland) and examined by Warmke and Blakeslee[5].

Recently, we have been able to study material collected by one of us (H. G. B.) in 1950 at Krossbu (alt. 1,340 m.) and Finse (alt. 1,500 m.), in Norway, the latter station being the type locality of Turesson's alpine ecotype of this species[3]. In addition to this sub-alpine and alpine Norwegian material, plants collected by Miss E. A. Baker, at a height of approximately 1,500 m. on the Weissenstein in Switzerland, have been grown and examined. All these thick-leaved plants (of both 'sexes') gave a diploid count with the usual complements of sex-chromosomes and autosomes. Their crossing reactions with each other and with British material are being examined; but all indications, so far, are that they do truly represent ecotypes of the single species *M. dioicum*. Therefore, it appears that Löve's tetraploid plant is not characteristic of the coastal and montane races of this species (which have remained at the diploid level), but is an aberrant. It would have been most interesting if the fate of this plant, representing a potential new race, could have been followed in Nature.

Unusual Features of the Root System of the Oil Palm in West Africa

On the deep acid sands of West Africa the roots of the oil palm (*Elæis guineensis*) may be divided into primary, secondary, tertiary and quaternary.

The primary roots emerge radially from the trunk-base and proceed for long distances without change in diameter. In palms over two years old this diameter is very constant (about 5 mm.). No roots have been found emerging at less than 15° from the soil surface. After proceeding downwards to a depth proportional to the angle they make with the soil surface, these primary roots tend to level out and travel horizontally for considerable distances (specimens from a 12-ft. palm have been traced for more than 40 ft. without coming to the end). They are completely unbranched and, in this soil, which is very free from obstructions, travel almost straight, occasionally tending to rise slightly. All primary roots found have been at a depth of more than 18 in.

The secondary roots emerge from the primary root within 45° of the vertical diameter, the sides of the primary roots being almost entirely clear. Of these secondary roots approximately 70 per cent grow vertically upwards and the remaining 30 per cent vertically downwards. The roots that grow upwards continue until they reach the soil surface, those growing downwards being of variable length.

The tertiary roots, which are probably the main absorbing roots, emerge at right angles from the secondary roots and travel in a horizontal plane. Their length is normally limited to about 10 cm., and the majority of them occur in the upper 10 cm. of the soil, where their length is also greatest. They do not occur in quite the same way on secondary roots growing downwards, as the tertiary roots tend also to continue downwards, producing an effect more like an unequal dichotomy.

The quaternary roots are very short (normally less than 5 mm.) and emerge at right angles to the tertiary roots.

Two other features of interest were noted: (1) The root system undergoes constant renovation, new primary roots emerging from the trunk base and old roots dying back from the tips. (2) New roots tend to grow along old dead roots. Whether the reason for this is nutrition or ease of spread remains to be proved by future experiments.

The importance of this type of root system to plantation practice is manifold. Thus mineral fertilizers do not need to be buried to become available to the plant, and, in fact, are likely to be more quickly and certainly absorbed if applied to the surface of the soil. Again, mechanical cultivation between the rows with implements such as disk harrows will do very little damage to roots, as the numbers of roots other than tertiary ones that will be cut will be very small.

My thanks are due to Messrs. Pamol, Limited, under whose auspices this work was done, for permission to publish this note.

Effect of Nitrogen-fixing Blue-Green Algæ on the Growth of Rice Plants

The fixation of atmospheric nitrogen by blue-green algæ has been reported by Pringsheim, Molisch, Drewes, Allison and Morris, De, Stokes, Bortels, Fogg, Burris and Wilson, Shioiri and Nishigaki *et al.*[1]; but no experiments on the effect of these algæ on the growth of rice plants have been performed.

About ten years ago one of us[2] began collecting blue-green algæ from the rice fields in various Far Eastern and South Sea regions. In the 643 samples collected, only thirteen blue-green species proved to be able to fix atmospheric nitrogen. These thirteen algæ grow abundantly in the tropical and semi-tropical regions of Java, Sumatra, Borneo, the Philippine Islands, Malaya, Indo-China, Siam, Burma, Hainan, Formosa and South China; but they are scanty in Japan, North China, Manchuria, Korea and Sakhalin. They belong to the genera *Tolypothrix*, *Nostoc*, *Schizothrix*, *Calothrix*, *Anabænopsis* and *Plectonema*. *Tolypothrix tenuis* (from Borneo), *Calothrix brevissima* (from Palau Islands), *Anabænopsis* sp. (from Sumatra) and *Nostoc* sp. (from Java) were the only ones of which bacteria-free cultures were obtained in a nitrogen-free medium (0·3 gm. K_2HPO_4, 0·2 gm. $MgSO_4 . 7H_2O$, 0·05 gm. $CaCl_2$, a trace of $FeCl_3$, 2 gm. glucose, and 1,000 c.c. distilled water). The total nitrogen fixed in 2 months was 9·6 mgm. in *Tolypothrix tenuis*, 5·2 mgm. in *Calothrix brevissima*, 3·4 mgm. in *Anabænopsis* sp. and 3·1 mgm. in *Nostoc* sp., estimated by the micro-Kjeldahl method.

With the help of such pure cultures the effect of these algæ on the growth of rice plants was examined

Table 1

Experiment	Length of leaves (cm.)			
	Tolypothrix tenuis	*Calothrix brevissima*	*Anabænopsis* sp.	Control
1	75·5	78·5	70·5	72 5
2	78 5	84·0	76·0	68·5
3	80·5	80·5	75·5	72·5
4	84 0	80·5	78 0	74·0
5	89·5	82·0	78 0	76 0
6	80·0	85·0	80 5	71 0
Mean	81·33	81·75	76·42	72·42
Variance	19·72	4·90	9 61	5·43
Standard deviation	4·44	2·21	3·10	2·33

in water-, as well as in pot-cultures[3,4], and in paddy-field experiments[5]. In the water-cultures with *Tolypothrix tenuis* the lengths of the leaves increased on an average by 17 per cent and the number of ears by 30 per cent. In pot-cultures with three of the blue-green algæ the effect on the lengths of the leaves is shown in Table 1.

As will be seen, the presence of *Tolypothrix* had a positive effect on the growth of the plants, the amount of nitrogen absorbed by them being 7·5 lb. per acre in excess of the control and the total nitrogen fixed at about 20 lb. per acre, while *Anabænopsis* produced no appreciable effect. In the paddy-field experiment *Tolypothrix tenuis* positively affected the growth of the plants, increasing the rice yield both in well-drained, as well as in badly-drained, paddy fields (Table 2).

Table 2

	Rice harvest (bushels per acre)		Percentage increase
Well-drained paddy field	non-inoculated	44·9	15
	Tolypothrix-inoculated	51 8	
Badly-drained paddy field	non-inoculated	30·3	25
	Tolypothrix-inoculated	37·8	

Full details will be published elsewhere.

Micro-electrode for Electro-physiological Work

THE micro-electrode described by R. A. Weale[1] necessitates the use of an electronic device, just for breaking the circuit, when the chain of silver crystals has reached the tip of the capillary tube. Furthermore, the micro-electrode proper has three disadvantages: (1) contact is easily disrupted in the capillary part; (2) resistance is comparatively high; (3) the electrolyte remains between the crystals. These disadvantages are a consequence of the 'feathery' or 'larchlike' character of the chain of silver crystals, which do not adhere sufficiently to one another.

We have prepared micro-electrodes in the following way. A capillary tube is drawn out by a method described by P. de Fonbrune[2]. The following stages are exactly in accordance with the method of Weale, except that we use silver nitrate instead of water in the tube. Then a plating bath is made of a drop of saturated silver nitrate on a tissue-culture slide (hollow ground). The bath is put on the table of the microscope, the tip of the capillary brought into the drop and observed with a high-power objective. The plating circuit is closed by bringing the silver wire anode into the drop as well. With a plating current of 1 V., very slow growth of relatively large silver crystals starts. As soon as the rate of growth exceeds the limit of being just perceptible, the plating voltage is reduced with an adjustable resistance. After about fifteen minutes, a few tenths of one volt will be sufficient to maintain the slow growth. Quicker growth suddenly produces the feathery chain. The indispensable watching of the growth of the crystals is fairly trying, as they take about 45 minutes to reach the tip. When the chain is finished, we break the circuit, an electronic device thus being dispensed with.

The result is a micro-electrode which is massively filled with silver. Consequently (1) contact is secured by the crystals adhering closely; (2) the resistance averages one ohm; and (3) no electrolyte remains between the crystals.

This method holds good for electrodes not smaller than 5 μ. Smaller tubes fill spontaneously with silver crystals. This curious phenomenon unfortunately produces crystal chains of the feathery type. We have not yet succeeded in solving this problem.

Bacterial Flagella

IN a recent communication in *Nature*[1], Weibull tends to regard my theory of bacterial motility as incorrect and as based on misinterpretation of observations made with dark-field microscopy. He confuses the issue, as so many do, by assuming that 'flagella' in different groups of bacteria mean the same thing, whereas in reality they often are structures *sui generis* in the various groups and may have very little or even nothing in common[2-4].

Weibull states that motile bacteria always have flagella; this is incorrect. He refers to Kauffmann's statement that *H*-serum immobilizes motile bacteria immediately, because it 'paralyses' their flagella. But my *observations* have shown that *H*-serum produces a precipitate on bodies and flagella which, after a determined struggle on the part of the bacteria, becomes so thick that motility gets less and less[6,7]. This purely mechanical progressive inhibition can be watched in a cinemicrographic film I made[8]. Weibull also mentions Ørskow's observation that *Proteus* bacteria on agar, covered with ink, can give the impression that their bodies lie still while their flagella whirl ink particles about. Flagella, however, were not actually seen, and it must be difficult to make sure that the bodies really are motionless; in any event, my contention that normally the body wags the flagella does not imply that nothing else can ever move them. Kingma Boltjes's work, also quoted by Weibull in support of his criticism, is invalidated by confusing the flagella of the large spirillums with those of typhoid and *Proteus* bacteria.

They are in entirely different categories, as I have shown[2-4,6]. One should not (and here I also think of electron microscopists) apply conclusions drawn from observations on spirillums and vibrios to the flagella of typhoid, *Proteus* and *subtilis* bacteria. In this letter I shall try to confine myself to a discussion of the latter bacteria. Weibull also mentions Fleming's experiments on penicillin-poisoned *Proteus* bacteria. I have repeated these experiments and made a film of them and find them inconclusive. I think these grotesque movements are more readily explained by bodily contortions. If flagella could perform in this way, they would require an elaborate system of co-ordination, something like a central nervous system.

Weibull agrees with Reichert's interpretation of the mechanical function of flagella. I have often pointed out[2-4,6,7,10-12] that Reichert never saw normal flagella functioning, at least not in typhoid and *Proteus* and suchlike bacteria. He himself states that he could only make their flagella visible with his darkground technique by suspending them in a colloidal solution. He imagined that the colloid just retarded motion and had an effect on refraction; but in reality, as I have repeatedly shown, it became adsorbed on the bodies and flagella, just like *H*-serum. What Reichert studied were live artefacts. Weibull's own *Proteus* flagella, coming from an agar medium and therefore growing in a colloidal medium, during growth are also covered with a sheath of agar. Weibull evidently does not know of and underrates *sunlight* darkground microscopy. It is only with sunlight darkground microscopy that I succeeded in making *naked* flagella and tails properly visible in broth or water[3,11-14]. By this technique, one can see the naked thin tail split into numbers of very thin flagella; this is entirely different from the picture on which Reichert and Weibull have worked.

With this sunlight darkground method[15] I have made further observations on the function of normal, that is, not artificially thickened, tails and their constituent flagella. There is the sudden reverse, the semi-somersault, the possibility of shaking off flagella by mechanical means after which swimming goes on undisturbed, the curious fact that the same bacterium will produce magnificent tails in one broth and none in another while motility is identical in both, and the definite spiral movement and shape of bacterial bodies (sometimes hidden by their high speed and then made visible by slow-motion filming). These studies, extending over twenty years, make it impossible for me to regard flagella as motor organs[2-16].

As a result of X-ray diffraction analysis of his flagella from *Proteus* and *subtilis* bacteria, Weibull places their proteins in the fibrous protein group, which comprises keratin and myosin. Chemical analysis gave him a low cystine and a high lysine content. This would fit in much better with myosin than with keratin. But chemical analysis of flagella from typhoid bacteria undertaken in my Department showed high cystine and low lysine content[17]. This would place flagella in the keratin group. I find it difficult not to consider that perhaps we are all analysing our respective nutrient media and not so much the flagella.

Weibull says the source of energy of flagella is obscure. This is not the only obscurity. Supporters of the motor theory of bacterial flagella do not commit themselves readily as to the origin of flagella. If they start in the protoplasm they must pierce the cell wall. In the case of peritrichous bacteria such as *Proteus*, this would mean dozens of holes. When are the new holes made, before or after cell division? After piercing the wall, the flagella must bend at right angles, run along the cell wall in close apposition, and at the end of the bacterium they must twist round one another to form a tail, which performs spiral movement. The mechanical implications of such an arrangement are extraordinary, and sudden reverses and semi-somersaults must cause awkward complications. If, on the other hand, the flagella arise outside the cell wall and yet are active motor organs, it follows that bacteria must have live active protoplasm both outside and inside the cell wall. These two masses of protoplasm evidently cannot directly communicate with one another and this creates an entirely novel situation in biology. The mechanical implications here are too formidable. My theory at least does away with difficulties of this kind. I do not claim that it is the last word on bacterial motility.

[16] Pijper, A., *J. Bact.*, 53, 257 (1947).
[17] Unpublished observations.

As any reader of Pijper's many works on bacterial flagella will soon discover, his opinions on this subject have changed considerably during the years. In the work from 1947, cited by me, bacterial flagella are described as "lifeless mucous twirls" or "polysaccharide twirls".

That the flagella of *Proteus vulgaris* are not mucous twirls or polysaccharide twirls is clear from chemical analyses and from X-ray investigations. It should suffice to mention their nitrogen content (16 per cent), and the near absence of carbohydrate (less than 0·2 per cent). From this it follows also that the *Proteus flagella*, prepared by me, are obviously not covered by a sheath of agar, as Pijper says.

As to the question of their role as motor organs, an excellent review of the different opinions on this matter is found in ref. 3. I am still convinced that the experiments of Ørskow, Kauffmann, Kingma Boltjes, Fleming, and others, carried out by independent methods, show that they are active motor organs.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, October 29

Institution of Electrical Engineers, Radio Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "The Social Implications of Television" (to be opened by Mr. F. H. Townsend).

Tuesday, October 30

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. Kathleen Lonsdale, F.R.S.: "Patterns".*

Royal Anthropological Institute (at 21 Bedford Square, London, W.C.1), at 5.30 p.m.—Miss Audrey I. Richards: "Tribal Admixture in Uganda".

University of London (at King's College, Strand, London, W.C.2), at 5.30 p.m.—Prof. O. Hassel: "Some Fundamental Problems in Structural Organic Chemistry and their Significance to the Chemistry of Substances containing Six-Membered Rings".* (Further Lecture on October 31.)

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.30 p.m.—Prof. R. A. Peters, F.R.S.: "The Scientific Basis of Medicine, 7, Biochemical Function of Vitamin B_1".* (Further Lectures on November 2, 5, 7, 14, 16, 20, 23, 27 and 29, December 4, 6 and 11.)

Society of Instrument Technology (at the Royal Society of Tropical Medicine and Hygiene, Manson House, Portland Place, London, W.1), at 6.30 p.m.—Mr. H. B. Moss: "Development of Materials for Instrument Manufacture".

Royal Aeronautical Society (at 4 Hamilton Place, London, W.1), at 7 p.m.—Dr. W. F. Hilton: "Supersonic Propellers".

Wednesday, October 31

Royal Statistical Society, Research Section (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.15 p.m.—Mr. P. Armitage: "The Statistical Theory of Bacterial Mutation".

Manchester Literary and Philosophical Society, Social Philosophy Section (at the Portico Library, Mosley Street, Manchester), at 5.30 p.m.—Mr. David K. Baxandall: "The Function of a City Art Gallery".

Physical Society, Colour Group (at the E.L.M.A. Lighting Service Bureau, 2 Savoy Hill, London, W.C.2), at 5.30 p.m.—Mr. P. Warburton: "The Appearance of Colours in Pattern Design".

Thursday, November 1

Physical Society, Optical Group (in the Physics Department, Imperial College of Science and Technology, Imperial Institute Road, London, S.W.7), at 3 p.m.—Scientific Papers.

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Scientific Papers.

Royal Institution (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Prof. E. N. da C. Andrade, F.R.S.: "The Physics of the Deformation of Metals". (Further Lectures on November 8, 15 and 22.)

Plastics Institute, North-Western Section (in the Great Hall, College of Technology, Manchester), at 6.30 p.m.—Prof. W. T. Astbury, F.R.S.: "Fibres and Chain-Molecules, Old and New". (Members of the Society of Dyers and Colourists are invited.)

Chemical Society (at Burlington House, Piccadilly, London, W.1), at 7.30 p.m.—Scientific Papers.

Friday, November 2

Physical Society, Acoustics Group (in the small Lecture Theatre, Science Museum, Exhibition Road, London, S.W.7), at 5 p.m.—Discussion on "The Calibration of Transducers by the Reciprocity Method" (to be opened by Mr. B. G. Butcher).

Royal Institute of Philosophy (at University Hall, 14 Gordon Square, London, W.C.1), at 5.15 p.m.—Prof. C. D. Broad: "Philosophy".* (Further Lecture on November 9.)

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.30 p.m.—Prof. D. Keilin, F.R.S.: "The Scientific Basis of Medicine, 8, Metal Catalysis and Intracellular Respiration".* (Further Lectures on November 5, 7, 14, 16, 20, 23, 27 and 29, December 4, 6 and 11.)

Institution of Works Managers (at the Waldorf Hotel, Aldwych, London, W.C.2), at 7 p.m.—Annual General Meeting.

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Sir John Cockcroft, F.R.S.: "Experiments with High Energy Nucleons and Quanta".

Friday, November 2—Saturday, November 3

Institute of Physics, X-Ray Analysis Group (at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2).—Conference on "The Structures of Silicate Minerals".

Saturday, November 3

Association of Scientific Workers, Agricultural Committee (at the Society for Visiting Scientists, 5 Old Burlington Street, London, W.1), at 3 p.m.—Sir William Slater: "The Training and Supply of Biologists".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Research Lecturer in Applied Physiology and Applied Psychology in the Nuffield Department of Industrial Health—The Registrar, King's College, Newcastle-upon-Tyne (October 31).

Principal (a good honours degree and teaching experience essential) of the Southend Municipal College—The Acting Chief Education Officer, Education Office, Warrior Square, Southend-on-Sea (November 1).

Chemist to carry out research on building materials at the laboratory in Wimbledon—The Director of Research, Railway Executive, Research Department, London Road, Derby (November 3).

Chemists at the Central Laboratory, Chiswick: (Ref. F/EV.186a) with experience or interest in general analytical work (excluding metallurgical analysis), (Ref. F/EV.186b) with experience or interest in technology of liquid fuels and lubricating oils—The Staff Officer, London Transport Executive, 55 Broadway, London, S.W.1, quoting the appropriate Ref. No. (November 3).

Demonstrator in Anatomy—The Registrar, King's College, Newcastle-upon-Tyne (November 3).

Generation Engineer (Construction), in the Eastern Division based at Divisional Headquarters in London—The Director of Establishments, British Electricity Authority, British Electricity House, Great Portland Street, London, W.1, quoting AE/212 (November 3).

Head of the Department of Electrical Engineering—The Registrar, Nottingham and District Technical College, Nottingham (November 3).

Junior Research Fellowships in Organic Chemistry—The Clerk to the Governors, Birkbeck College, Breams Buildings, London, W.C.1 (November 3).

Lecturer in Applied Mathematics—The Registrar, The University, Sheffield (November 3).

Lecturer in the Department of Electrical Engineering, Oldham Municipal Technical College—The Director of Education, Education Offices, Oldham (November 3).

Lecturer (with an engineering degree and suitable industrial experience) in the Department of Mechanical Engineering, capable of teaching Thermodynamics and Hydraulics to students studying for the Higher National Certificate and Final B.Sc. (Engineering)—The Principal, Acton Technical College, High Street, Acton, London, W.3 (November 3).

Lecturer in Geology—The Secretary, The University, Edinburgh (November 3).

Lecturer in Metallurgy at the Technical College of Monmouthshire—The Director of Education, County Hall, Newport, Mon. (November 3).

Lecturers (science graduates) in the Department of Education—The Secretary, International Wool Secretariat, Dorland House, 18–20 Regent Street, London, S.W.1, endorsed 'Confidential' (November 3).

Mining Engineer to take charge of the sinking, surface workings and development of a large colliery in the South-Western Division—The Divisional Establishment Officer, National Coal Board, South-Western Division, Cambrian Buildings, Mount Stuart Square, Cardiff (November 3).

Scientist (mycologist or botanist, with good honours degree or equivalent qualification, and experienced in microscopical examination of timbers) in connexion with the study of the degradation and methods of preservation of structural timbers, especially in cooling towers—The Secretary's Office (Establishments), Applications Section, British Electricity Authority, British Electricity House, Great Portland Street, London, W.1, quoting AE/210 (November 3).

Lecturer in the Department of Veterinary Pathology—The Registrar, The University, Liverpool (November 5).

Plant Pathologist—The Registrar, Wye College, Wye, Ashford, Kent (November 5).

Principal Scientific Officer (Sociologist) in the User Requirements Division of the Building Research Station (at present stationed in South Kensington), to undertake research into the relationship between design of buildings of all types and the requirements of their occupants—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4084/51 (November 8).

Principal Scientific Officers in the Royal Naval Scientific Service: (*a*) at the Underwater Countermeasures and Weapons Establishment, Havant—Physicist with considerable experience in the development of electronic amplifiers and similar devices together with a wide experience of magnetic and electromagnetic apparatus and a thorough knowledge of eddy current phenomena in various conducting media, to lead a group of scientists engaged on the development of electric and electromagnetic devices; (*b*) at the Naval Construction Research Establishment, Rosyth—Physicist able to take charge of a division carrying out applied research in connexion with underwater explosives, gun and rocket blast and the effect of these on ships' structures; (*c*) at the Naval Construction Research Establishment, Rosyth—Engineer familiar with modern techniques of load strain measurements and with a sound knowledge of the design and theory of structures to undertake both small- and large-scale investigations and experiments involving the mechanical testing of structural assemblies in steel—The Secretary, Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4080/51 (November 8).

Head of the Department of Science (Grade I), Reading Technical College—The Clerk to the Governors, Education Office, Blagrave Street, Reading, Berks (November 10).

Assistant Lecturer in Chemistry—The Registrar, Trinity College, Dublin (November 10).

Senior Lecturer and a Lecturer in the Postgraduate School of Mining—The Registrar, The University, Sheffield (November 10).

Senior Scientific Officer (with an honours degree in organic chemistry and some research experience, preferably of synthetic work) in the Biochemistry Department—The Secretary, Hannah Dairy Research Institute, Kirkhill, Ayr (November 12).

SCIENTIST I (with a good honours degree in chemistry, and have studied physics, engineering or fuel technology to degree standard, with considerable experience of research in heavy industry) to lead a team on pilot plant and associated research on carbonization, at the Central Research Laboratories, Stoke Orchard, Cheltenham—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, endorsed TT/382 (November 14).

PROFESSOR OF PHILOSOPHY, and a LECTURER (Grade I) or SENIOR LECTURER IN MATHEMATICS, at the University of Tasmania—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 15).

VETERINARY SURGEONS in the Field and Research branches of the Department of Veterinary Service, Southern Rhodesia—The Secretary, Southern Rhodesia Government, 429 Strand, London, W C.2 (November 15)

LECTURER IN PATHOLOGY and an ASSISTANT LECTURER IN PHYSIOLOGY, at Makerere College (University College of East Africa)—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (November 17).

RESEARCH OFFICER (with University degree with honours in science or applied science, with physics or physical chemistry as major subject, or equivalent qualifications) IN THE DIVISION OF INDUSTRIAL CHEMISTRY, Fishermen's Bend, Melbourne, to undertake investigations on the reactions and equilibria in gasworks and/or metallurgical refractories—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting No 3580 (November 17).

SENIOR STATISTICIAN at the Waite Agricultural Research Institute of the University of Adelaide, to assist in the design and interpretation of the experimental programme of the Institute, and to give introductory lectures in statistical methods in the Faculty of Agricultural Science—The Registrar, The University, Adelaide, Australia (November 30).

AERONAUTICAL AND MECHANICAL ENGINEERS (Ref. Est. 5c/48) at the Ministry of Supply in London and elsewhere, for the planning and progressing or control of production or inspection of air and marine craft and ancillaries and of related machine tools, gauges and armament, AUTOMOBILE AND MECHANICAL ENGINEERS (Ref. Est 5c/49) in London and elsewhere, for the planning and progressing or control or inspection of wheeled and tracked vehicles and components, MECHANICAL ENGINEERS (Ref. Est.5c/52) in London and elsewhere, for the design and development or standardization or planning and progressing or control of production or inspection of air and marine craft and installations, wheeled and tracked vehicles, etc.—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting O 536/51AA and the appropriate Ref No.

ASSISTANT BIOCHEMIST (B Sc. graduate in chemistry, hons. degree desirable) IN THE DEPARTMENT OF CLINICAL PATHOLOGY—The Secretary, United Manchester Hospitals, Royal Infirmary, Manchester 13.

ASSISTANT TEACHER (with graduate or equivalent qualification) OF CHEMISTRY AND PHYSICS and related subjects, in the Department of Science, Sheffield College of Commerce and Technology—The Director of Education, Education Office, Sheffield 1

CHEMISTS AND METALLURGISTS (Experimental Officer grade) at a Ministry of Supply research establishment in Berkshire · METALLURGIST (Ref. F.591/51A) with research experience in electrodeposition or in the investigation of the properties of metallic films and coatings, PHYSICAL CHEMIST or PHYSICIST (Ref. F.592/51A) with interest and preferably experience in work on ceramic materials—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No.

CHEMISTS (Senior Scientific Officer grade) (with a first- or second-class honours degree in chemistry or equivalent qualification, preferably with explosives or propellent experience) at Ministry of Supply London headquarters, for work concerned with guided weapons—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C 2, quoting F.723/51A.

ELECTRICAL ENGINEER (young university graduate, with research outlook) to join a team working on aircraft de-icing—The Employment Officer, National Research Council, Sussex Street, Ottawa, Ont., Canada.

ENGINEER at a Ministry of Supply establishment at Bickley, Kent, to be responsible for inspection of radio fuses and some development work—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting D.435/51A.

ENGINEER at a Ministry of Supply establishment in Hants, to run a 10,000 kW gas turbine power station and control a substation with 40 M V A , 33 kV grid intake and associated factory H.T. distribution—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting D 465/51A.

EXPERIMENTAL OFFICERS in various Royal Ordnance Factories. (a) in Somerset (SENIOR EXPERIMENTAL OFFICER, EXPERIMENTAL OFFICERS and ASSISTANT EXPERIMENTAL OFFICERS, Ref. F.724/51A) for work connected with the manufacture of explosives and acids and routine analysis of a more intricate nature, (b) in Ayrshire (ASSISTANT EXPERIMENTAL OFFICER, Ref. F 725/51A) for chemical analysis and experimental work, supervision of chemical testing of high explosives and related substances, (c) in Lancashire (EXPERIMENTAL OFFICER, Ref. F 726/51A) for laboratory work, (d) in the London area (ASSISTANT EXPERIMENTAL OFFICER, Ref F.727/51A) for chemical analysis of ferrous and non-ferrous metals and alloys and works control of ferrous and non-ferrous metallurgical processes—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W C 2, quoting the appropriate Ref No.

EXPERIMENTAL OFFICERS or ASSISTANT EXPERIMENTAL OFFICERS, in the Ship Division of the National Physical Laboratory (Department of Scientific and Industrial Research), Teddington, for experimental work in the Ship Tanks—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting C.613/51A.

FISHERIES OFFICER (with a University degree in natural science, preferably zoology, and a real interest in natural history) in the Agricultural Department, Tanganyika, to investigate the potentialities of marine fishing along the coast of Tanganyika, and types and habits of fish in these waters, etc.—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting 27404/10/51.

GRADUATES IN PHYSICS OR MATHEMATICS (with first- or second-class honours) as METEOROLOGISTS in Nigeria—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. No. 27118/4/51.

HEAD OF THE DEPARTMENT OF ENGINEERING AND MINING, Wakefield Technical College—The Director of Education, 27 King Street, Wakefield.

IRRIGATION ENGINEER IN THE DEPARTMENT OF WORKS AND HYDRAULICS, Trinidad—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S W.1, quoting Ref. No 27322/228.

JUNIOR INVESTIGATOR (with B Sc., or equivalent, in metallurgy) for work on the welding of alloy steels—The Secretary, British Welding Association, 29 Park Crescent, London, W.1

LECTURER (Grade I) IN COTTON SPINNING—The Principal, Technical College, Paisley

MICROBIOLOGIST or BIOCHEMIST (postgraduate, preferably with several years research experience) to take part in research work, mainly on the mode of action of antibacterial agents—The Secretary, Wright-Fleming Institute, St. Mary's Hospital Medical School, Paddington, London, W.2.

OBSERVER (based in Trinidad) to take charge of seismological recording stations to be set up in Windward and Leeward Islands—The Under-Secretary of State, Research Department, Sanctuary Buildings, Great Smith Street, London, S W 1.

PHYSICAL CHEMIST (degree in chemistry essential, and some research experience in electrochemistry or corrosion an advantage) for research in the Electrochemistry Section of the Laboratories at Sketty Hall, Swansea—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1

PLANNING ENGINEER to undertake the detailed construction planning of sections of large factories and to follow up construction and installation progress—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs.

PRINCIPAL SCIENTIFIC OFFICER (with a good honours degree and some research experience) IN THE ENGINEERING DIVISION, to undertake investigation of problems associated with the mechanical harvesting, handling and processing of underwater seaweed—The Secretary, Institute of Seaweed Research, Inveresk, Midlothian.

PRINCIPAL SCIENTIFIC OFFICER (with a first- or second-class honours degree in physics· a wide general physics background is essential) at the Ministry of Supply London headquarters, for the co-ordination of physical research for guided weapons and evaluation of progress in new techniques for potential application to weapon projects—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W C 2, quoting A.293/51A.

RESEARCH ASSISTANT for dissection studies on cereals—The Director of Research, Research Association of British Flour Millers, Cereals Research Station, Old London Road, St. Albans, Herts.

RESEARCH ASSISTANT to carry out experimental work on the effect of adsorption on the strength of solids, under the supervision of Dr S. J. Gregg—The Registrar, University College, Exeter.

RESEARCH ASSISTANT (Scientific Officer grade, with appropriate honours degree, or equivalent), to take part in studies mostly concerned with use of chicks in nutritional research—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, Berks, quoting 51/5.

RESEARCH OFFICER (with degree in physics, or equivalent) for work on full- or semi-scale plant, eventually to supervise technical investigations on dust and pulverizing, and a RESEARCH OFFICER (with degree in physics, or equivalent, and experience in the finer techniques of physical measurement and of electronics desirable)—The Assistant Secretary, Ref. A.4, British Coal Utilisation Research Association, Randalls Road, Leatherhead, Surrey.

RESEARCH SUPERINTENDENT—The Secretary, Linoleum Research Council, Roxburghe House, 273 Regent Street, London, W.1.

SENIOR EXPERIMENTAL OFFICER or EXPERIMENTAL OFFICER at the Royal Aircraft Establishment, Farnborough, for the design and development of small clockwork mechanisms and associated small electro-mechanical devices—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C 2, quoting C.405/51A.

SENIOR LECTURER IN AIRCRAFT DESIGN—The Registrar, College of Aeronautics, Cranfield, Bletchley, Bucks, endorsed 'Senior Lecturer in Aircraft Design'.

SENIOR LECTURER IN PHYSIOLOGY in the Department of Pharmacy, Bradford Technical College—The Director of Education, Town Hall, Bradford.

SENIOR SCIENTIFIC OFFICER (Ref. E 503/51A) for engineering development and research covering a wide range of structures and mechanisms, a SENIOR EXPERIMENTAL OFFICER (Ref. E.504/51A) for work on the design of steel and alloy structures, including the mechanical testing of metals and some metallurgical examinations, and an EXPERIMENTAL OFFICER (Ref. E.505/51A) for engineering development and research, at a Ministry of Supply establishment in the South of England dealing with the design and development of military bridging and associated equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C 2, quoting the appropriate Ref No.

UNIVERSITY GRADUATES IN MATHEMATICS, PHYSICS, ENGINEERING, or GEOGRAPHY (including Geodesy) as SURVEYORS, Tanganyika—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S W 1, quoting Ref. No 27076/21/51.

UNIVERSITY GRADUATES IN PHYSICS, MATHEMATICS and ENGINEERING, for Permanent Commissions or for Short-Service Commissions in the Education Branch of the Royal Air Force—The Air Ministry (A.R.1), Kingsway, London, W.C.2.

LEADERSHIP, EDUCATION AND TECHNOLOGY

IN his lecture on August 20 on higher technical and scientific man-power in Great Britain in the series of centenary lectures on the worker in industry, arranged by the Ministry of Labour and National Service, Lord Hankey remarked that in his wide experience in peace and war the qualities of 'leadership' and 'character' are harder to find and are even more important than technical capacity. Similarly, his earlier Romanes Lecture on "The Science and Art of Government" emphasized that since government is primarily concerned with human beings, human relations and human personality are dominating considerations. Whatever measures are taken to introduce the humanities to the curriculum for students of science and technology, whether at the undergraduate stage or before entry to the university, Lord Hankey's suggestion for broadening the outlook and experience of those destined for positions of high administrative responsibility in the world of science and technology presupposes that the universities and technological institutions in which they were originally trained do, in fact, receive in the first instance a fitting proportion of the ablest minds in each generation.

In an article on "Research in the Universities" published much about the same time (*Universities Quarterly*, August), Prof. A. R. Ubbelohde expressed a similar view: except where their professional qualifications make it absolutely essential, scientific workers in Britain do not occupy public positions in proportion to their native talents. It is true that some, quite apart from any administrative qualities they may or may not possess, are indisposed to deal with administrative duties: they would endorse whole-heartedly Sir Cyril Hinshelwood's forthright declaration that the man of science is in peril of being overwhelmed by the mass of administrative work. That danger exists, and some pruning of the proliferation of committees and other administrative work within and without the academic world may well be required. There will remain, however, an irreducible minimum of administrative responsibilities, and if these are not discharged by the scientific men themselves, they must be carried out by those who can at least understand the outlook and the method of science as well as its findings. Otherwise, as Prof. Ubbelohde rightly insists, in this technological civilization very wasteful and damaging situations can arise.

During the past twenty years, the annual Walker Trust Lectures at the University of St. Andrews on leadership have dealt with various aspects of leadership—its nature, the way it is exercised in different walks of life, and above all its functioning in a democratic society. In one of the earliest of these Lectures*, Dr. J. R. Mott referred to the way in which his travels throughout the world had made him conscious of a demand the world over that the universities should equip and send forth into all walks of life more young men and women for the leadership of the constructive forces of the world; and in the latest of these Lectures (see p. 769), dealing with the universities and cultural leadership, Sir Walter Moberly urges that to educate for leadership is still a primary duty of universities, and to get such an education should be one of the chief motives which bring students to them.

---

* Walker Trust Lectures on Leadership, delivered before the University of St. Andrews, 1930–49. Pp. viii+286. (London: Oxford University Press, 1950.) 15s. net.

Under the influence of the German ideal of the university as an institution for extending the realm of knowledge, attention has been concentrated in the modern universities of Britain on research rather than on education, and sometimes, indeed, the latter has not been clearly differentiated from instruction. Outside the ancient universities, the idea that universities are institutions for educating men and women whose abilities suggest that they may hold high positions in life was not readily accepted. Even to-day, when both ancient and modern universities are fully alive to the importance of both research and educational duties and of the interrelation of these two functions, the idea of education for leadership is unpopular in the presence of the strong equalitarian views prevalent in our society. Confused thinking on this issue has discouraged discussion of the idea of education for leadership; attention has been forced upon the subject by outspoken comments at discussions on higher technological education and at conferences organized by the universities themselves and industrial bodies such as the Federation of British Industries.

In these circumstances, Dr. Eric James's "Education and Leadership" makes a timely appearance*. It is a brief but brilliant analysis of the problem of leadership in a democratic society, and the difficulties which attend attempts at selection. Dr. James discusses in some detail the education of the brilliant individual, and in particular he deals with the contribution of the boarding school. In these chapters he raises debatable issues, but they are large issues and deserve the attention not of the educationist alone but also of the industrialist, the man of science, the politician and all who are concerned with the continuance of democratic institutions in the Welfare State.

Dr. James's first chapter, in which he discusses at length various aspects of leadership in a democratic society—the reasons for the distrust of democratic communities of the idea of an élite and the whole conception of leadership, the factors which have made leadership so important in the complex and technical situations of modern civilization and the conditions which must be satisfied for leadership to be acceptable in our society—is a fine and challenging piece of work. It is worthy of setting beside any of the lectures included in the recently published volume of Walker Trust Lectures, not excepting even those by John Buchan, Lord Moynihan, Dr. Hensley Henson, Lord Montgomery, Earl Wavell, or Sir Richard Livingstone.

High intelligence, in Dr. James's view, is the key to the type of leadership which is competent to meet the highly complex and technical situations that confront us to-day. He does not minimize the value of character: on the contrary, he recognizes a purely materialistic view of life as more serious than the dangers of new weapons of destruction. The removal by science and technology of many material obstacles to right living imposes great demands upon spiritual leadership, because the attitude of most men to fundamental questions of moral and æsthetic judgment must depend to a very considerable degree upon the values accepted and proclaimed by a minority of exceptional individuals.

Dr. James is fully aware of the difficult problems which here confront us in our dependence for advance upon the individual, or the creative minority, at a time when authority is rejected and the validity of individual judgment accepted. He does not, however, discuss further their implications, and the way in which the dependence of effective leadership in a democratic community upon persuasion as well as upon a belief in equality of opportunity and wide diffusion has made training for leadership even more imperative. The responsible leadership which such factors, as well as the rapid development of science and technology, demand cannot be achieved, even with high intelligence, without training. These must be acquired, through common living as well as through education, mental habits of freedom, equitableness, calmness and moderation, and the power to understand men and to lead them.

In this chapter Dr. James directs attention to the social problems that are involved, once it is accepted that leadership in any field calls for recruitment of those with high intelligence. Some of our fundamental assumptions and practices will require discarding as the educational ladder is perfected and the risk of talent being unrecognized disappears. However repugnant a democratic community may feel towards the idea of special schools for leadershi it must recognize, as Dr. James insists, that if societ is forced to place authority and responsibility in th hands of certain individuals, education has no mor urgent task than to see that those individuals are so far as is possible, adequately prepared for thei tasks.

The concern over higher technological educatio indicates that this point is appreciated in one secto of the field; but there is plenty of evidence to sho that its general implications are by no means commonly accepted. There is a real danger that equalit in education may come to mean—and not merely i the comprehensive secondary school—the limitin of opportunity for those abler children on whom th nation greatly depends. It is easy to point to instance of defective leadership in almost every sector of th national life: able leadership in the industrial o technical field can scarcely exert its full influenc unless it is matched by equally wise leadership in th trade unions and in the political field. Not the leas important feature which makes Dr. James's book 'tract for the times' is its analysis of the difficultie which in our present system attend the education of the most gifted individuals, and of the implications for to-day of the Platonic conception of education.

---

* Education and Leadership. By Eric James. Pp. 112. (London: George G. Harrap and Co., Ltd., 1951.) 6s. net.

Dr. James is not afraid of raising debatable issues, but he shows convincingly exactly why it is important that those who are destined to become leaders in government, in science and in industry must be exposed to the influence of first-rate minds and given the opportunity of growing in an environment designed to meet their needs. We can, he remarks, legitimately demand from our leaders that they shall have devoted at least some thought to certain perennial and fundamental problems of individual and social life. Ideally, they should have arrived at a coherent philosophy and a basis of principle in the light of which they will make their judgments. Some studies are manifestly more likely than others to force young men and women to grapple with these general questions of politics and æsthetics, of morals and metaphysics, and to encourage them to submit their standards of value to constant scrutiny. In the nature of things, the young scientific worker or technologist will learn more of what is in the minds of men, the thoughts that have always excited and the enduring traditions, from history, philosophy and literature, than he can from his own subject, no matter how fine that may be as an intellectual discipline.

It can scarcely be altogether fortuitous, Dr. James points out, that the course of study most conspicuously successful in producing the highest kind of leadership is also that in which the student is bound to concern himself with the greatest questions of human conduct and social obligation. He does not deny that there are many scientific men who are at least as wise in their political and moral judgments as their colleagues who have studied the humanities. Nevertheless, it is much easier for an individual in some schools and all universities to study chemistry, for example, and never have to ask himself what he means by justice, or what are the limits of his obligation to the State, than if he had studied history or philosophy. If such an individual comes to occupy a position of authority he is to this extent less well equipped, and for that reason it may be questioned whether the policy of higher technical education which was outlined in the White Paper of September 20 will do anything to supply higher technologists of the quality really required. Still more important is the question whether a policy of entrusting such education to the technical colleges will ensure that t is carried out by teachers of sufficiently high standing. On the importance of that factor, not only Dr. James but also the majority of participants n the debate on higher technological education have nsisted; and it is notable, as the recent discussion in Edinburgh showed, that even those who are most anxious to see the task entrusted to the technical colleges are doubtful whether, in fact, without a transformation of the whole structure of the technical colleges, rendering them independent of the local authorities, it will be possible to provide those conditions of academic freedom as well as of remuneration which will attract teaching staff of the requisite calibre.

Higher technological education is only one of the problems which this book illumines, and like the Walker Trust Lectures on leadership it contains much wisdom to guide us in shaping our future policy, both there and in the expansion of the universities. Vocational education is inescapable, and its extension at the universities may be unavoidable. We may be called upon to determine more carefully the nature of good vocational education, but that the universities will continue to be places of vocational education and that young men and women should seek earnestly to prepare themselves within a university for vocations to which they wish to devote their lives is, as Prof. G. B. Jeffrey emphasized in his Eddington Memorial Lecture, wholly admirable.

Nevertheless, neither the universities nor the colleges of technology can accede to all the demands now being made upon them for the provision of new forms of training without their structure and character being profoundly changed. The universities must discover some principle of decision, rooted in their own tradition, on which they can give an answer to these demands. Prof. Jeffrey suggested that this might be found by appealing to the characteristics which in his view should be the mark of a university: a temple of knowledge, one and indivisible; inspired by a social purpose, and a place in which young people are prepared in body, mind and spirit for service in other spheres. To justify vocational training in a university, a profession must therefore show that the field of knowledge requisite for its exercise is a part of the integrated body of knowledge for which the university is trustee; that this general body of knowledge would be manifestly incomplete if it failed to have regard to these professional studies; and that these professional studies could not be adequately pursued except in living contact with the greater body of knowledge. A profession that can meet this test is rightly described as a learned profession, and can further make some contribution towards giving a student a worthy conception of the great body of knowledge of which the university is itself a symbol.

That, after all, is one central point. We may presuppose that through a wise and rigorous selection the universities receive a fitting proportion of the ablest intellects of each generation. We must recognize, too, that the engineer or physicist trained in a university is marked out as a potential leader, at least in his chosen profession, and for that leadership he needs education. Part of that education must be social, and for that duty to be discharged the universities must find new forms, appropriate to our time, of giving social expression to the unity of knowledge in the fellowship of learned men. But the need still remains for liberalizing vocational education, and for ensuring that in every scientific and technological course appropriate place is found for the humane studies, with the insight they afford into the minds of men.

STRUCTURAL INORGANIC CHEMISTRY

Structural Inorganic Chemistry

By A. F. Wells. Second edition. Pp. xi+727. (Oxford: Clarendon Press; London: Oxford University Press, 1950.) 35s. net.

Anorganische Strukturchemie

By Prof. W. Hückel. Pp. xv+1033. (Stuttgart: Ferdinand Enke, 1948.) 71.20 DM. (£5 10s. 0d).

Structural Chemistry of Inorganic Compounds

By Prof. Walter Huckel. Translated by Dr. L. H. Long. Vol. 1. Pp. xiii+437. (New York and Amsterdam: Elsevier Publishing Co., Inc.; London: Cleaver-Hume Press, Ltd., 1950.) 70s.

In his foreword to "Anorganische Strukturchemie" Prof. W. Huckel states that "this work attempts to furnish inorganic chemistry with that which organic chemistry has long possessed as a basis for its systematization, namely, a structural and constitutional theory in one embracing representation", while in "Structural Inorganic Chemistry" Dr. A. F. Wells has a less ambitious aim based on his conviction that the structural side of inorganic chemistry cannot be put on a sound basis until the results of X-ray crystallography and other techniques of investigating structure have been incorporated into chemistry as an integral part of that subject. With these aims the two books inevitably cover a good deal of common ground, but they differ considerably as a result of the authors' different outlooks, and this not only in content but also in the nature of the approach. In particular, whereas in general Dr. Wells is content to let the facts speak for themselves and is careful to make quite clear what are facts and what is speculation, Prof. Hückel frequently adopts the style of the advocate, and in some cases belabours those whose views do not please him with what seems to me to be unnecessary vehemence; moreover, in reading some of Prof. Huckel's discussions, a student would find it very difficult to decide whether the examples given were based on experimental facts or merely inferences from theory.

The second edition of Dr. Wells's book follows the same general plan as the first edition, but in addition to being expanded by about 25 per cent it has been considerably improved in various respects. Part 1, consisting of six chapters dealing with such matters as covalent bonds and their properties, the crystalline state, and the experimental methods of structural chemistry, has been somewhat reduced in length, chiefly by omitting a chapter on the structure of the atom and shortening one on states of aggregation. By passing quickly over subjects on which there is already an extensive and easily accessible literature, the author has thus been able to give a much more satisfactory treatment of a number of topics to which he scarcely did justice in the first edition; for example, a student reading the second edition can now obtain an understanding of some of the contributions of thermodynamics to structural chemistry, and when he encounters a new concept he will now find either an explanation in the text or a good reference to its more extended treatment elsewhere.

Part 2 contains a systematic description of the structures of most of the important classes of inorganic compounds. The additions to our knowledge in this field since the first edition appeared have been very great, and the formula index of the book now contains nearly twice as many entries as before. The text of Part 2 has, however, increased by less than 50 per cent, and Dr. Wells has very successfully incorporated the new matter without loss of clarity in the general treatment; a valuable feature of the book is that bond-lengths and other data are presented critically so that, for example, the student can see clearly to what extent a particular structural theory is supported by the experimental facts.

The production of the book is of the high standard expected of the Clarendon Press, and I have not noticed any misprints. The price has increased only in proportion to the size and still remains remarkably low, particularly having regard to the wealth of excellent illustrations which the book contains. The provision of numerous references to the original literature in the form of footnotes is a considerable improvement, and the two indexes (formula and subject) are adequate, although those who, like myself, take a minor delight in the eponymic nomenclature of inorganic chemistry will note with regret that old friends such as Fremy's and Reiset's salts are not allowed to appear in the subject index but must take their places with the common herd in the formula index.

In retrospect I feel that in devoting a large part of my review of the first edition of Dr. Wells's book (see *Nature*, 157, 386; 1946) to remarks on some of its shortcomings, I did less than justice to its positive merits; in acknowledging this, it is a pleasure to express the opinion that the second edition retains all the merits of the first and scarcely any features which could be described as defects even by the most exacting critic.

A great many people would wish Prof. Hückel success in his attempt to provide a single all-embracing structural and constitutional theory for inorganic chemistry, not least those numerous students who go up to universities with a disinclination for inorganic chemistry because "it isn't systematic like organic chemistry", and it is therefore of some interest to inquire whether Prof. Hückel's book is likely to appeal to such students. It should perhaps first be asked whether it is intended to do so, and the answer to this is not easy to find. The author explains that he wrote various parts of the book at different times as monographs, in part at least to familiarize himself with the topics concerned, and this, together with his obvious conviction of the value of his method of approach for the development of the subject, suggests that the book is addressed to mature workers in chemistry. In assembling the parts into the finished book, however, additional matter seems to have been added to make the work suitable as a text-book. The result is a most interesting and unconventional book, but not in my opinion a successful one; indeed, to embark on a task such as Prof. Huckel has attempted requires a belief in an inherent simplicity in Nature which, if it exists, is at present obscured by too many hard facts.

Prof. Hückel takes the view that while the Periodic System probably gives as good a basis as any for the classification of inorganic substances for elementary study, classification based on bond types is better for the advanced worker; and he believes further that the Werner co-ordination theory, which is valid for a high proportion of inorganic compounds, should be given much more prominence in this classification. This view underlies the plan of the book and the development of most of the themes in it, and, while the resulting treatment has much to commend it (and indeed in many respects is not so novel as Prof. Huckel seems to think), it is pursued too exclusively, so that the book as a whole is unbalanced. Thus while the author concedes that kinetic and thermodynamic studies have much to contribute to inorganic chemistry, he devotes relatively little space to such matters (entropy is not mentioned), and when he warms to his theme he is apt to deny virtue to anything but stereochemistry. Apart from the lack of balance in treating existing knowledge, such an attitude may have the unfortunate consequence of persuading its holder that the main object of future work is to provide confirmation for a theory.

The work is divided into three books: (1) stoichiometry and systematization, (2) atomic structure and chemical bonding, and (3) structure and constitution. Book 1 opens with a good historical survey and then discusses the basis of systematization—the co-ordination theory, valency and bond types, and Werner's work. It concludes with a chapter of about 140 pages on complex compounds in which the author illustrates the application of the co-ordination theory to double salts, salt hydrates, inner-complex compounds, multinuclear compounds, polyacids, etc. Book 2 deals with the Periodic System, atomic structure, methods of investigating bonding, and the nature of the chemical bond. This section is very unbalanced and very uneven in quality; for example, in the chapter on methods fifteen pages are devoted to molecular volumes and only two to electron diffraction, and the account of several of the methods is neither sufficiently clear to be suitable for a student nor critical enough to be useful to an advanced worker. Book 3 contains chapters on inorganic molecules and volatility, crystal chemistry, silicates and glasses, metals and alloys, and chemical reactions. These chapters contain a wealth of material and make very interesting reading, but they contain more errors than one would expect, some merely irritating and others definitely misleading.

A student taking up this work will find much that is interesting, although not much that he cannot find elsewhere; he will almost certainly not feel that the new approach offered him is appreciably more systematic than that which he has known previously—the canvas is too vast and the book attempts too much. Some advanced readers may find the treatment attractive, but it does not make the book particularly easy to use as a work of reference, even with the help of the excellent indexes; the style is frequently turgid and too often inclined to be polemical (of five references to a well-known pre-war text-book, four are made in order to criticize).

The first volume of Dr. L. H. Long's "Structural Chemistry of Inorganic Compounds" contains Books 1 and 2 of Prof. Huckel's work, and it is unfortunately necessary to say that it is a very bad translation. A rather large number of misprints mar an otherwise beautifully produced book; but, in addition, many errors have been introduced by the translator (as, for example, "more frequently" for "vielmehr", making nonsense of the sentence in which it appears). Dr. Long explains in his foreword that the unusual complexity of the original language has given him difficulties; but a translator can scarcely be regarded as discharging his task adequately when he gives an almost word-for-word translation of a difficult German sentence to produce such a monstrosity as "The force of affinity was supposed to exhibit itself between dissimilar particles as, for example, the reaction between acid and base teaches". Still less can he be excused for mis-translating the German into such sentences as "This fact is expressed here by the nature of the opposing forces in the representation selected for the maintenance of stable structural arrangements through the equilibrium of forces". These examples are among the worst I have encountered; but on nearly every page there is some clumsy construction, error of translation or misprint, with an occasional grammatical error or spelling mistake, so that the book makes very irritating reading.

E. G. Cox

MAN IN BRITAIN THROUGHOUT THE AGES

A Natural History of Man in Britain

Conceived as a Study of Changing Relations between Men and Environments. By H. J. Fleure. (New Naturalist Series.) Pp. xviii+350+64 plates. (London and Glasgow: Wm. Collins, Sons and Co., Ltd., 1951.) 21s. net.

It need scarcely be said that anything Prof. H. J. Fleure writes is worth reading. The book is clearly not intended for the specialist, as its range both in time and subject-matter is enormous; but it will doubtless appeal to schools and the general public interested in the study of man throughout the ages in the British environment.

More than half the available space is taken up with a history of England from the Stone Ages until modern times, and, as this half consists of only 181 pages, even Prof. Fleure's excellent summary can but be in the nature of a sketch. On the other hand, the next chapter, which deals with people and their racial make-up, is a first-class piece of original work, the result of long years of research undertaken with the help of the Leverhulme Trust. A chapter on clothes throughout the ages, and others on dwellings, villages and towns follow. The one on dwellings, especially, contains much general information on early types of habitation. There follows a chapter on the church and the castle, concerned not only with architecture but also with religious and lay organizations throughout the period. The book concludes with a brief account of the changes in means of transport and the alterations and rises in population in the countryside and towns. As has been said, whatever Prof. Fleure writes is interesting; but it is rather sad that only in Chapter 9 does opportunity occur for him to give an account of his original researches in a subject of which he is an acknowledged master.

There are numerous excellent photographic illustrations, thirty-eight of them in colour. Frankly, the latter are the less satisfactory. The colours are not too good, and the subjects in many cases irrelevant. It is difficult to see why a colour plate should have been devoted to a Highlander teaching a boy to play the pipes; nor can one be very excited about a small farm-house near Snowdon merely because it is entitled, "House of a man who married a fairy"—neither have much relevance to the text. The half-tone illustrations are better chosen and well reproduced and include some really lovely photographs. The line-drawings of such objects as stone implements are entirely inadequate. This is to be regretted, as one such sketch figures the chalk idol found many years ago by Mr. Leslie Armstrong at Grimes Graves and which I fancy has never up to now been illustrated. One gets the unfortunate impression that the illustrations have been included rather to catch the eye of a would-be purchaser than to illustrate the text. The book is very readable, and one can be full of admiration for Prof. Fleure, who certainly set himself a difficult task.

M. C. Burkitt

THEORIES OF THE VISUAL THRESHOLD

Les théories photochimiques classiques et quantiques de la vision et l'inhibition nerveuse en vision liminaire.

Par Ernest Baumgardt. Pp. 61. (Paris : Éditions de la *Revue d'Optique théorique et instrumentale*, 1950.) 300 francs.

Since the pioneer work of Hecht, Shlaer and Pirenne on the significant part played by the quantum nature of light in the perception of threshold light stimuli, a number of workers, including the author of this little book, have applied themselves enthusiastically to the full exploitation of the idea. M. Ernest Baumgardt belongs to those who believe that *two* or more light quanta must be absorbed within a certain small time-interval and within a certain retinal area if perception of the stimulus is to ensue. The experimental results which it is sought to explain on this hypothesis consist of measurements of the absolute threshold as a function of the exposure time and the area of the test stimulus. The second half of the book is, in fact, devoted to new measurements of this kind by the author, dealing in the main with the effect of stimulus area for both foveal and extra-foveal vision and employing blue- and deep-red stimuli to separate the rod and cone responses.

So far as the variation of threshold with exposure time is concerned, the central hypothesis is not entirely adequate, the deviations being in the direction one might expect if the minimum number of quantum absorptions for perception exceeded two. The author is able to show, however, that a possible explanation is obtained on the following lines. The neurone receiving the pulses from the receptors which have absorbed light quanta is assumed to be thrown into a state of facilitation following the absorption of the first light quant. This lasts for a critical time τ, and if within this time a second quant is absorbed the neurone discharges and perception ensues. But if the second absorption is delayed beyond the time τ, the neurone passes into a refractory state and, even though a third quant may be absorbed within a time τ after the second, there is no discharge and no perception. For extrafoveal vision the effect of area on the threshold is found to accord well with the central hypothesis, the critical area corresponding to about 45′ diameter for rod vision and 8′ diameter for cone vision. For foveal vision the situation is complicated by the inhomogeneity of the receptor network. It is remarkable—and this criticism applies not only to the present work—that investigators of areal summation rarely make any attempt to explore the uniformity of the threshold over the retinal region under study by point-to-point observations with a small test stimulus.

Some interesting comments are made by M. Baumgardt on the notion that as the level of adaptation of the retina is raised the progressive modification of visual functions such as differential sensitivity is associated with a steady reduction in the concentration of photosensitive substance (visual purple for rod vision) in the end-organs. He vehemently rejects this view, at least for levels up to about one lumen per square metre. While we may not be prepared to go all the way with him, his arguments seem worthy of careful consideration. Unfortunately the style in which the book is written is a little repelling : it tends to oscillate between the dogmatic and the obscure. This is a pity, as M. Baumgardt's views should prove stimulating to all workers in the subject.

W. S. Stiles

FUNCTION THEORY

Leçons sur la théorie des fonctions

Par Émile Borel. (Collection de monographies sur la théorie des fonctions.) Quatrième édition. Pp. xiii+296. (Paris : Libr. Gauthier-Villars, 1950.) 1200 francs.

Leçons sur les nombres transfinis

Par Prof. Waclaw Sierpiński. (Collection de monographies sur la théorie des fonctions.) Nouveau tirage. Pp. 240. (Paris : Libr. Gauthier-Villars, 1950.) n.p.

The great collection of monographs on the theory of functions, directed by Émile Borel, was inaugurated in 1898 by his own "Théorie des fonctions", of which the present work is a fourth edition. Although the substance of the book has not changed much, and is therefore more than fifty years old, it is still perhaps the most inspiring introduction for the young student to the concepts of aggregates, measure and modern theories of integration, concepts the development of which can be traced back to the stimulus of Cantor's work on "Mengenlehre". The new edition contains some additional matter in notes and in a new appendix, all tending to emphasize Borel's own philosophical position with respect to current controversies on the foundations of mathematics.

Borel has always held the view that definitions which are not constructive, numbers which cannot be calculated, descriptions which do not define, are insecure pillars in a mathematical edifice, though his scepticism is not carried to the extreme position occupied by Brouwer and his school. If, as he says, the result is that the pupils of his pupils regard him as a reactionary, it is because his own work and teaching have been extraordinarily stimulating.

The reprint of Prof. W. Sierpiński's tract on transfinite numbers in the Borel collection is welcome. The author was the acknowledged master of the virile Polish school of real-variable theory, and his account of the transfinite cardinals and ordinals is clear, precise and succinct. While Sierpiński's main logical position is almost flatly opposed to Borel's, the series of Borel monographs would have been sadly incomplete without some account of Cantor's fundamental work on transfinite numbers, and no one was better fitted than Sierpiński to write such an account. Since the techniques employed are in themselves not of great complication, the book can be read and enjoyed, without much previous acquaintance with the topic, by anyone with a taste for fantastic logical adventures of a severely abstract type.

ALCHEMY AND ALCHEMISTS*

By Prof. JOHN READ, F.R.S.

The Nature of Alchemy

MOST people who think about alchemy in the present age (and there are not many who do) regard it as the pretended art of transmuting base metals, such as lead, into the noble ones, silver and gold. Liebig held the view that alchemy was never anything else but chemistry; from this point of view one may look upon alchemy as the chemistry of the Middle Ages. In its widest and truest significance, however, alchemy was a grandiose philosophical system which aimed at penetrating the mysteries of creation and of life; it sought to place the microcosm of man in adjustment with the macrocosm of the universe; the transmutation of one form of inanimate matter into another was merely an incidental alchemical goal.

The more one studies alchemy, the more complex it appears. It was, indeed, a vast network of rudimentary chemistry, interwoven with philosophy, astrology, mysticism, theosophy, magic, and many other strands. The associations of alchemy with religion and with psychology still offer wide fields of study; in recent years C. G. Jung, in particular, has expressed the opinion that alchemy is no less important to psychology than to chemistry.

Alchemy endured for more than a millennium, that is to say, from at least early Christian times until the end of the seventeenth century. But alchemy has long been outmoded, and so there is little realization at the present day of the extent to which alchemical conceptions and imagery permeated the thought and art of the Middle Ages.

Sketched in broad outline, the fundamental ideas of alchemy were, first, that all forms of matter are one in origin; secondly, that these forms are produced by evolutionary processes; thirdly, that matter has a common soul which alone is permanent: the body, or outward form, being merely a mode of manifestation of the soul, is transitory and may be transmuted. Here are views which in their essentials bear a remarkable resemblance to those of modern physical science. Indeed, in this twentieth century "modern alchemy", as Lord Rutherford called it, has shown the possibility of bringing about many transmutations of elements.

Alchemical reasoning was mainly deductive and based on two *a priori* assumptions: first, the unity of matter; secondly, the existence of a potent transmuting agent, known as the Philosopher's Stone. From the postulate of the unity of matter it followed that this medicine of the metals became also the medicine of man. In this guise the Philosopher's Stone was known as the *Elixir Vitæ*, or Elixir of Life.

From this summary it should be clear that alchemy was much more than an experimental science. It was a philosophical system. In their true significance, the efforts made by the adepts to transmute metals were attempts to prove the truth of the broad philosophical system of alchemy by means of material experiments.

Origin of Alchemy

The universal patron adopted by the alchemists from early times and throughout the Middle Ages was Hermes Trismegistos, or Hermes the Thrice-Great. In this Greek equivalent of the Egyptian Thoth, the deified intellect, the alchemical fraternity recognized the father of the Hermetic Art and the author of the Emerald Table. The thirteen precepts of this Table formed the articles of association of the so-called "Sons of Hermes": it laid down in cryptic language the guiding principles of their creed.

Thoth, as depicted in ancient Egyptian temples, was sometimes shown with the *crux ansata* (the symbol of life) in the right hand, and a staff in the left. Linked with the staff were a serpent, a scorpion, a hawk's head, a circle, and an asp. Each of these representations had its particular symbolical meaning. Such symbolism was later characteristic of alchemy; and even modern chemistry, the daughter of alchemy, is to a large extent a science of symbols.

The origin of alchemy has often been ascribed to Egypt, otherwise known as Khem, the Biblical Land of Ham. Sometimes it has been supposed that alchemy arose farther to the east, in Chaldea, or even in China. The Chaldeans, as exponents of astrology, associated the sun, moon and planets with specific metals, and also with human organs and destinies. Still farther east, in ancient China, alchemical ideas may be traced as early as the fifth century B.C. in the comprehensive religious and philosophical system known as Taoism. Much later, in the first century A.D., Wei Po-Yang, "the father of Chinese alchemy", wrote the first treatise in Chinese dealing with alchemy, in which he described the preparation of the "pill of immortality", otherwise the *Elixir Vitæ*.

The ultimate origin of alchemy is thus a vexed question. There is little doubt, however, that alchemical knowledge and ideas were gathered from the ancient civilizations of Egypt, Babylonia, India, and China, and brought to a focus in Greece. From Greece this corpus of alchemy was transmitted to Islam, mainly through Syria and Persia. Eventually the accumulated knowledge of the Muslim alchemists, drawn from these various sources and augmented in its passage through Islam, was brought into Western Europe, chiefly through Spain.

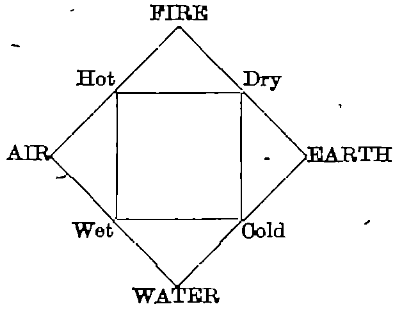
Alchemical Theory

Alchemy, like modern science, had its guiding theoretical principles. The fundamental theory of alchemy was that of the Four Qualities and Four Elements, often represented in a diagram formed of an outer and an inner square (see p. 760).

The corners of the outer square carry the names of the four elements: fire, earth, water and air. The corners of the inner square, situated at the mid-points of the sides of the outer square, are allocated to the four fundamental qualities: the hot, the dry, the cold, and the wet. The diagram shows that fire is hot and dry; earth, dry and cold; water, cold and wet; air, wet and hot. These four elements may

---

* Substance of a discourse delivered on August 10 to the British Association for the Advancement of Science meeting at Edinburgh.



The four qualities and the four elements

also be looked upon as representing energy (fire) and the solid, liquid and gaseous states of aggregation of matter (earth, water, air).

This theory, usually ascribed to Aristotle, may be traced in Egypt and India as far back as 1500 B.C. It is the oldest theory of physical science, and it was very widely held, in one form or another, over a long period. It bears out the statement that "there is a great oneness in the human mind in the matter of broad principle in crude cosmical ideas".

According to the theory, water—one of the four elements of the material world—is an embodiment of cold and wet qualities. When the cold quality is replaced by the hot one, the element water is changed into the element air, embodying the wet and hot qualities. The idea of transmutation is thus implicit in the theory. Nowadays, of course, this process is viewed simply as a change of liquid water through the agency of heat into the gaseous form of the same substance, and there is no question of transmutation.

In essence, this ancient theory is based upon a primitive mode of thinking sometimes known as the Doctrine of the Two Contraries. This is dependent upon the recognition of a distinction between opposites, such as cold and hot, dry and wet. An apposition of outstanding importance in alchemy was that of the two opposed, or contrary, elements—fire and water. These two opposites came to light in a new guise in the sulphur–mercury theory of the metals, which seems to have been propounded by the Muslim alchemists in the ninth century A.D.

The principle here known as "sulphur" was essentially an embodiment of combustibility, and "mercury" denoted the mineral spirit of metals and also liquidity or fusibility. It was held that when these two natural principles, engendered in the bowels of the earth, came together in a state of purity the result was gold; if they were slightly impure they gave silver; if they were markedly impure they furnished only the baser metals. Beyond this, it was supposed that in states of superfine purity they could give rise to something so much purer than ordinary gold that a small amount of this product (the Philosopher's Stone) would be able to transmute a very large quantity of a base metal into gold of ordinary purity.

The chief experimental task of the alchemical adept was to imitate, and even surpass, Nature in accomplishing such changes.

In the cryptic expression and symbolic representation of alchemy, sophic sulphur and sophic mercury (as the two principles were often called) assumed many forms. For example, they were known as Osiris and Isis, sun and moon, Sol and Luna, brother and sister, masculine and feminine, active and passive, giver and receiver, fixed and volatile, wingless lion and winged lioness, and so forth.

It was supposed by the esoteric alchemists, or adepts, that the pure "seeds" of gold and silver (or quicksilver) could be extracted from these metals in the form of sophic sulphur and sophic mercury. These "seeds" could then be combined, often in a liquid menstruum, to yield the Philosopher's Stone. The succession of processes here concerned was known as the Great Work, leading to the preparation of the Philosopher's Stone, or Grand Magisterium. The Stone, resulting from the union of masculine and feminine principles, was often symbolized as an infant.

According to these views, in order to prepare the Philosopher's Stone an initial quantity of gold was necessary. The Stone (often described as a red powder) could then be used to convert base metals into more gold, so that the original gold was "multiplied", as the alchemists used to say. One of their favourite metals for "multiplication" was mercury, and this choice has been curiously vindicated by modern observations that gold can indeed be produced by transmutation from mercury, although only in excessively minute amounts and at great cost.

In modern parlance it would be correct to call the Philosopher's Stone a catalyst. Here again the alchemists are vindicated; for what more potent catalyst could be imagined than the neutrons which start and maintain the explosive disintegration of uranium-235 into other elements? "Every thing possible to be believ'd," wrote the English poet and mystic, William Blake, "is an image of truth. . . . What is now proved was once only imagin'd."

Alchemical literature abounds in cryptic descriptions and pictorial representations of the blending of sophic sulphur and sophic mercury in the synthesis of the Stone. For example, a wingless lion and winged lioness are shown in playful conflict, with a watery background (representing the liquid menstruum, or Hermetic Stream); an alchemist is depicted in the act of balancing equal weights of fire and water; the Hermetic Androgyne—half man, half woman—stands above a dragon, signifying the menstruum.

Incidents from the Bible and from classical mythology were also freely adapted to alchemical ends. Thus, in an illustrated manuscript in the St. Andrews collection, the birth of Eve from Adam's rib, with the Serpent as onlooker, is depicted to symbolise the same fundamental idea as the Hermetic Androgyne. As an example of another kind, taken from a different source, Apollo and Artemis, with the terrorizing serpent of Juno, are selected from classical mythology in order to furnish a further pictorial illustration of the same conception. Some alchemists went so far as to insist that the whole corpus of classical mythology was nothing more than a complex medium designed expressly to record alchemical truths in concealed allegories and "abstract riddles of our Stone", as Ben Jonson phrased it in his play, "The Alchemist" (1612).

Alchemical Symbolism

Pictorial symbolism is an ingredient of the first importance in alchemy. Many of the designs were characterized by colour schemes suggestive of heraldry. Among medieval examples, the so-called "figures of Abraham the Jew", dating from the early years of the fifteenth century, were held in great reverence by alchemists of succeeding ages. These figures were ascribed to Nicolas Flamel, a Parisian alchemist of great repute; they took the form of a series of elaborate frescoes, decorating the arcade of the churchyard of the Innocents in Paris. The designs, executed in colour, were capable of a dual alchemical and religious interpretation. The Biblical story of the massacre of the innocents by King Herod formed a central feature of the series. Herod was pictured as "a King with a great Fauchion". Mothers were shown in the act of weeping "at the feet of the unpittiful Souldiers; the bloud of which Infants was put in a great vessel, wherein the Sun and Moon came to bathe themselves". In other words, infants' blood was merely a cryptic representation of the liquid menstruum which was supposed to aid in the conjunction of sophic sulphur and sophic mercury.

As another example, an illustration entitled the "First Key of Basil Valentine" (c. 1600) shows a king and queen as the central feature. Below the king a wolf leaps over a heated crucible, and near the queen an old man with a wooden leg manipulates a scythe around a cupel. An accompanying "explanation" directs the operator: "Take a fierce grey Wolf. Cast to him the body of the King, and when he has devoured it, burn him entirely to ashes in a great fire. By this process the King will be liberated; and when it has been performed thrice the Lion has overcome the Wolf, who will find nothing more to devour in him. Thus our body has been made fit for the first stage of our Work."

The alchemical wolf, *lupus metallorum*, was "antimony" (stibnite, or native antimony sulphide), used in the heated crucible as an agent for purifying gold, since it "devoured" traces of metallic impurities. The wooden-legged ancient signified Saturn, that is to say, either the slow-moving planet of that name or the dull, heavy metal, lead. The scythe, like other sharp implements, symbolized fire. This part of the design therefore represents the cupellation of argentiferous lead, furnishing pure silver. In brief, the First Key of Basilius shows how to begin the preparation of sophic sulphur and sophic mercury, in readiness for the next operation of the Great Work.

Probably the finest artistic examples of the avowed symbolism of alchemy are the beautiful copper-engravings of Johannes Theodorus de Bry and his associates; these occur notably in various alchemical works of Count Michael Maier, such as "Atalanta Fugiens" and "Symbola Aureæ Mensæ", published at Oppenheim and Frankfurt during 1617–18. These plates are boldly engraved: textures are conveyed by different systems of shading; human figures are drawn forcefully and correctly; the compositions have an effect of brilliance and solidity, enhanced by strong modelling and shadows.

Apart from such *ad hoc* pictorial representations of alchemical tenets, a strong alchemical influence pervaded much of the art of the Middle Ages. It found expression repeatedly in the painting, decorative architecture, sculpture and coloured glass of this era. Alchemical ideas and symbolism may be traced in detail, for example, in the work of such artists as Durer, Cranach, Giorgione and Campagnola. It may even be claimed that every detail in Durer's masterpiece of engraving, "Melencolia" (1514), is capable of an alchemical interpretation: the doctrine of melancholy is inseparably bound up with the Saturn mysticism which permeates alchemy[1].

Decline of Alchemy

The outstanding practical aim of alchemy until the sixteenth century was the transmutation of base metals into gold, whether from purely philosophical or mercenary motives. Early in the sixteenth century Paracelsus endeavoured to give a new direction to operative alchemy by insisting that its main goal should be the healing of disease rather than the making of gold. He envisaged alchemy as a handmaid of medicine, to be applied in the preparation of chemical remedies of mineral origin. He sought to liberate medicine from the obsession of the ancient Galenic order, and in this sense he takes rank beside such contemporaries as Luther, Copernicus and Columbus as an emancipator of mankind from the trammels of authority. The ensuing period of iatro-chemistry or medico-chemistry, lasting until the eighteenth century, witnessed a slow decline of the old alchemy.

Paracelsus was essentially a reformer and propagandist of the Renaissance. His chief contribution to alchemy was his modification of the sulphur–mercury theory by the introduction of a third principle which he named salt. In his system of the *tria prima*, or three hypostatical principles, sulphur, mercury and salt stood materially for inflammability, metallicity and uninflammability (fixidity) and mystically for the soul, spirit and body of man. The second half of the seventeenth century found both the old alchemy and iatro-chemistry on the wane. Despite their excesses, both the alchemists and the iatro-chemists had done a great deal to accumulate chemical knowledge and to prepare the way for the incipient science of chemistry which was to arise in the second half of the eighteenth century.

It is sometimes held that the publication of "The Sceptical Chymist" by Robert Boyle in 1661 heralded the end of alchemy. It is true that Boyle dismissed to his own satisfaction in this famous book the systems of the four elements and the *tria prima* and put forward the modern idea of an element; but the emergence of modern chemistry had to wait for more than another century. "During this Indian summer of alchemy the stage was held by the Theory of Phlogiston, while the four elements and the three hypostatical principles hovered behind the scenes like ghosts reluctant to be laid. Phlogiston, an imagined inflammable principle present in all combustible bodies, was essentially a revival of sophic sulphur, claiming noble descent from the Sun god of the primitive religions. Phlogiston melted finally 'into air, into thin air' with the discovery, in the second half of the eighteenth century, of the chemical composition of the ancient 'elements' air and water and of the true nature of combustion. These discoveries ushered in the era of modern chemistry."[2]

Types of Alchemists

The term 'alchemist' has been used throughout the ages to denote men, of many kinds, with a real or professed knowledge of alchemy. These ranged from impostors and charlatans having no claim to the title, through puffers (*souffleurs*), goldmakers, skilled practicants, and scholastic philosophers, to adepts and religious mystics.

Simon Forman (d. 1611), the original of Ben Jonson's alchemist, Subtle, was a typical charlatan, gaining a livelihood by imposture and having a mere smattering of alchemical knowledge. The puffers—so called from their unintelligent addiction to the bellows—were uninformed "labourers in the fire", exoteric exponents of alchemy who were animated solely by avarice: their number was legion. Some of the goldmakers were indistinguishable from the puffers; but others, possessing a definite grasp of the principles of alchemy, occupied a higher position in the alchemical hierarchy. Goldmakers were often attached to courts and subsidized by princely patrons. One of the most picturesque of this kind was Damian, alchemist to James IV of Scotland, and Abbot of Tungland in Galloway. Damian, who is said to have been a Lombard, varied his alchemical experiments in Stirling Castle by undertaking one of the earliest experiments in artificial flight, with the aid of a pair of wings made of feathers. He took off in September 1507 from the lofty battlements of Stirling Castle; but, according to a contemporary account, "shortlie he fell to the ground and brak [broke] his thee bane [thigh bone]". In the true alchemical manner he attributed this result to the substitution, in his wings, of eagle's feathers by hen's feathers, "which yearned and coveted the mydding [dunghill] and not the skyis [skies]".

Scotland figures a good deal in the history of alchemy. Also in Scotland there are some outstanding collections of alchemical literature, particularly the Ferguson and James Young Collections in Glasgow, and others in St. Andrews, Edinburgh and Aberdeen. A century after Damian's exploit, Scotland produced a mysterious itinerant goldmaker in the person of Alexander Seton, otherwise known as "The Cosmopolite". He has also been called "the chief martyr of alchemy"; for his dramatic career is said to have ended in tragedy at Cracow in 1604, as a result of his experiences in the torture-chamber of the Elector of Saxony at Dresden[3].

The numerous paintings of alchemists and alchemical interiors, notably by Brueghel, Stradanus, Teniers, Steen, Wijck and other artists of the Low Countries, are mainly concerned with alchemists of the kinds that have been mentioned[4]. Such genre representations of these painters and of artists in Italy, Spain, Germany and other countries, are of great interest and value to historical science.

Alchemists of a severely practical type, who were interested chiefly in chemical phenomena and in the discovery and application of new substances and processes, are typified by such men as Brunschwick, Agricola, Libavius and Glauber; the scholastic philosophers by Roger Bacon and Albertus Magnus; and the religious mystics, who viewed alchemy as "the Divine Art", by Ripley and Khunrath.

Alchemical Music

Among the mystical alchemists, Count Michael Maier calls for special mention. He was physician, private secretary, and alchemist to the Emperor Rudolph II (the so-called "German Hermes") at Prague, early in the seventeenth century. A man of many accomplishments, Maier was also a philosopher, mystic, classical scholar and musician. He was a voluminous writer of great credulity, and he carried to extremes the alchemical interpretation of Egyptian and classical mythology. This subject forms the chief theme of his "Atalanta Fugiens" (1618), a quaint and fascinating work handsomely embellished with fifty copper-engravings by de Bry and his school. Each engraving is provided with a cryptic title and a Latin epigram written in elegiac couplets. Each epigram is set to music, in the form of so-called "fugues", which are in reality canons in two parts against a repeated *canto fermo*. In allusion to the classical legend, these three parts are termed, "Atalanta, or the fleeing voice", "Hippomenes, or the pursuing voice", and "The apple in the path, or the delaying voice".

Presumably, in view of the alchemical belief in the beneficent influence of music, the final processes of the Great Work, carried out in the sealed Vessel of Hermes and directed by prayer as well as by chemical and astrological influences, were sometimes undertaken to the accompaniment of musical chants or incantations. To the religious mystics among the alchemists these processes would partake of the nature of a religious ritual, and it would be natural for them to introduce music from one of these closely related activities to the other. It must be emphasized also that alchemical theories and ideas came largely from ancient Greece, and that the alchemists followed Pythagoras and Plato in ascribing a particular importance to number and harmony in the interpretation of Nature and the universe.

In 1935, some of these alchemical canons[5] were sung in public for the first time by members of the St. Andrews University choir, at the Royal Institution in London. Fuga XVIII may be mentioned as typical. The Latin epigram begins:

> *Si quod agens fuerit natura, mittit in orbem*
> *Vires atque suas multiplicare cupit . . .*

"Whatever active principle there is in nature, it sends out its force in all directions and loves to multiply the same." It is of interest that some manuscript notes of "Atalanta Fugiens" made by Sir Isaac Newton, and now in the St. Andrews collection, bear a special mark of emphasis beside this particular epigram.

A METHOD OF MAKING VISIBLE THE DISTRIBUTION OF ACTIVITY IN A SOURCE OF IONIZING RADIATION

By PROF. W. V. MAYNEORD, R. C. TURNER, S. P. NEWBERY and H. J. HODT

Physics Department, Royal Cancer Hospital, London

FROM the medical point of view, probably the most important physical question in relation to the use of radioactive isotopes is finding their distribution in the body. If we are interested in diagnostic applications, then clearly this is the main problem which faces us. What we want to know is where the material goes, how quickly it gets there, and generally what is its natural history. If we are interested in the therapeutic use of radioactive isotopes, then the problem has a double significance inasmuch as the spatial distribution of the material is also the basis of the radiation dosimetry. The only method of defining uniquely the distribution of the material is to use measuring or detecting systems with strongly marked directional properties. The usual procedure of taking an insufficiently protected Geiger counter with a wide aperture is quite inadequate for deducing the precise distribution of radioactive material.

In a recent publication, Mayneord and Belcher[1] have described how a scintillation counter may be used in the examination of various simple sources, and have verified the theory that such a directional system measures approximately the 'thickness' of radioactive material. In many instances we do not require, however, an accurate determination of the distribution of radioactive material, but we do require to know its approximate position and extent. It would, in these instances, be a great convenience if, instead of having to make multiple observations with a Geiger counter, draw 'equinumeral surfaces' and so deduce radiation distribution, we could obtain a visual image of the distribution of material. With such ideas in mind about six months ago, we started to construct apparatus in an attempt to form such visual images.

Apparatus

Imagine a detector in a well-canalized system receiving radiation from only a small angular region, and moving in front of a source so as to scan it. Then the instantaneous counting-rate at any moment will be proportional *inter alia* to the radioactive material 'seen' at that moment. If now we produce on a screen a brightness proportional to that instantaneous counting-rate, and if also we write a matrix synchronized with the scanning, then we build up a picture of the distribution of radioactivity.

The problem of observing the radiation through a small aperture presents difficulties, particularly with an extended source. If discrimination with respect to position is to be good, that is, if resolution of the picture is to be adequate, then we can only allow a very fine aperture; such an aperture, however, 'sees' only a small amount of radioactivity and the sensitivity of the system may therefore be very low.

The apparatus we have developed consists of three parts: (*a*) a mechanical scanning unit, (*b*) a pulse-shaping and integrating network, and (*c*) a display system.

The mechanical scanning unit (Fig. 1) comprises a head housing the detecting system, and capable of being moved so as to scan a preselected field uniformly and repetitively. This head consists of a block of lead of roughly elliptical cross-section, having in it three channels carrying respectively two Geiger counters and an optical system for producing a visible spot of light corresponding to the area 'seen' by one of the counters. The main protection of the counters is afforded by cylindrical blocks of tungsten alloy of high atomic number and having a density of approximately 16. These blocks have a length of approximately 6 cm., each block being about 3 cm. in diameter. Apertures of either 5 mm. or 3 mm. diameter have been drilled through this protective material, and the radiation detected reaches the counter through one of these apertures. The head design is, in practice, a compromise between the demands of protection of the counter, on one hand, and, on the other, adequate sensitivity and mobility, the latter being of particular importance inasmuch as this heavy head has to be moved backwards and forwards accurately and consistently. The motion of the head is effected in our apparatus by rotating cams driven by a motor via a chain of gears. Two cams are so arranged that one produces a rotation about a vertical and the other about a horizontal axis. By careful design it was found possible to obtain relatively smooth motion with approximately uniform velocity. In this way (Fig. 2) the Geiger counter head, pivoted on an equatorial mounting, is made to move backwards and forwards, left to right and right to left, one complete cycle taking two seconds. We find experimentally that the beam retraces its path accurately and scans an approximately rectangular area the extent of which may be recorded by exposing photographic material in the path of the light beam.

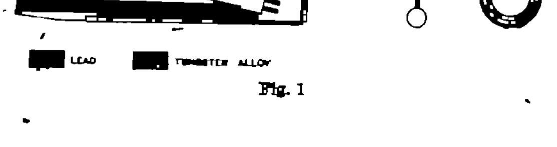

Fig. 1

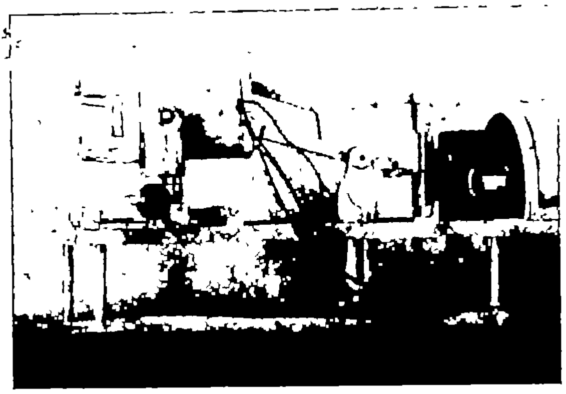

Fig. 2

A matrix of one hundred spots is obtained by two mechanical rotary switches driven from the motor. These switches select, in sequence, a series of potentials which are applied to the deflecting plates of the cathode-ray tubes in synchronism with the motion of the head. In this way we have applied ten potentials, thus deflecting the spot horizontally by ten consecutive steps. At the end of a line of ten spots the second switch comes into operation and deflects the spot one step vertically over a series of ten vertical steps. In this way we obtain a rectangular matrix of one hundred spots written downwards in a time of ten seconds. In early experiments we were impressed with the magnitude of the background even with a high degree of protection, and decided, therefore, to attempt to subtract this background automatically; hence the two counters in the head, one for main counting, the other to record the background and attempt to subtract it. In practice, we have found that in many circumstances background subtraction is not satisfactory, due to the asymmetry of the source with respect to the two counters; but if the source is at a fair distance from the head, the method appears to be fundamentally sound.

The pulses from the counter are first fed into a univibrator, the outgoing pulses of which, of constant size, then pass through a transitron pulse-shaping circuit. This network is necessary for the control of contrast in the final picture, since we obtain from the transitron circuit pulses of adjustable width, enabling us to obtain over a very wide range any required

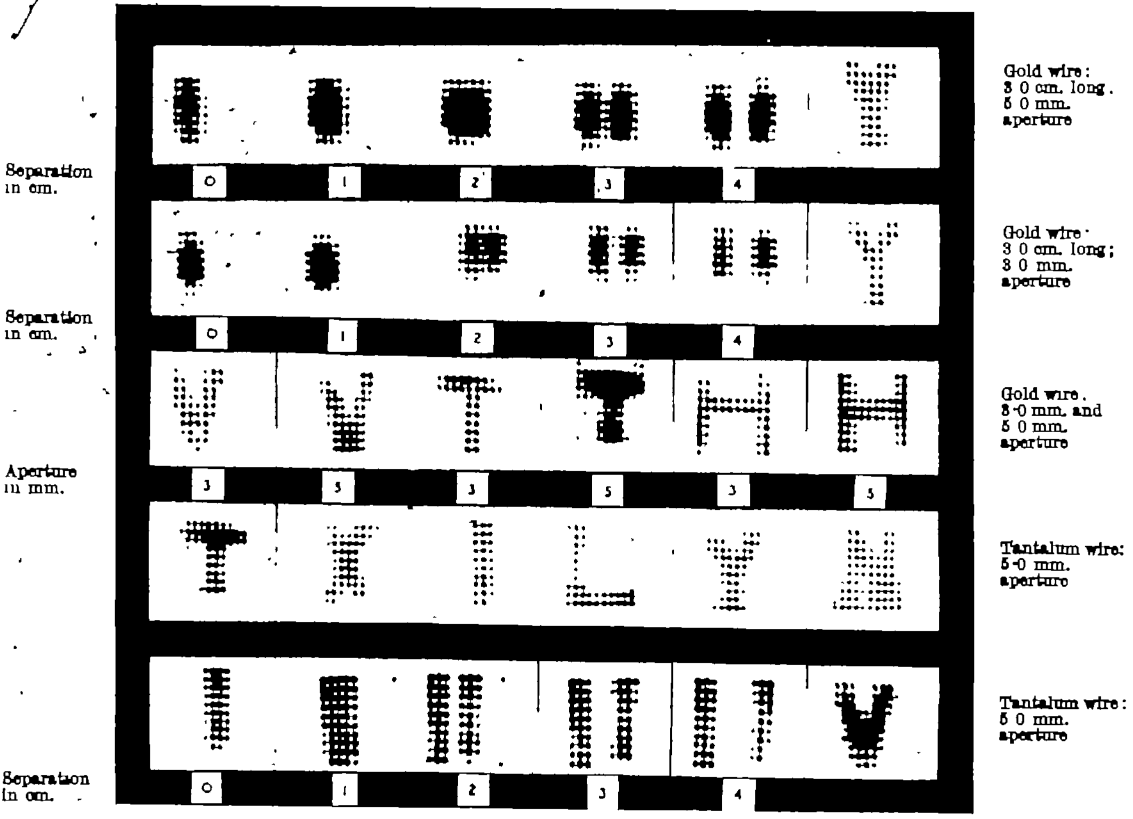

Fig. 3. Images of radioactive sources

D.C. voltage from a given number of pulses. The pulses from the transitron are then fed via a cathode-follower to the integrating circuit.

There are many possible methods of integrating these pulses and obtaining a proportional direct current. We have tried two of them, one using a simple time constant arranged to be slightly less than the duration of a single spot (that is, one tenth of a second), and a second method consisting of feeding groups of pulses corresponding to consecutive spots into consecutive condensers, and selecting resulting D.C. potentials in sequence with a mechanical switch. Experiments have been carried out with both systems, but at the present stage of development of the apparatus the former is simpler, though the latter should eventually give more accurate quantitative results. With either system we produce a D.C. voltage which is approximately proportional to the number of pulses which have occurred in the counting channel during the previous tenth of a second. By means of a balanced modulator driven by a local low-frequency oscillator, an output A.C. voltage of this same frequency is obtained the amplitude of which is fairly accurately proportional to the D.C. voltage. We may now feed this A.C. voltage into an amplifier of adjustable gain and take this amplified voltage through condensers to the control grids of the display oscilloscopes, one having a long-persistent screen for visual study and the second a blue screen for photography.

Some Theoretical Considerations

Some theoretical consideration has been given to the problems of the geometry of the systems of detection. Briefly, we may say that if we have a small point source and a detector of linear dimensions smaller than those of the aperture through which the radiation is coming, then we observe a fall in counting-rate in accordance with the inverse square law. If the source is still small and the detector fills the aperture, we still have inverse square law, but now to the aperture and not the detector. If, as is usually the case, the emitter is large enough to fill the aperture, then the conditions become more complex. If the source is, for example, a plane sheet of uniformly radioactive material and of infinite area, then as the source moves away the area 'seen' by the detector increases as the square of the distance, the radiation from each element decreases in the same ratio and the number of counts remains constant. If the source is linear the total amount of material 'seen' by the detector at any one time is approximately proportional to its distance from the aperture. We have verified experimentally that such relationships exist in practice. Simple calculations lead us to expect that in order to form a satisfactory visual image the detector of our system must 'see' at any moment approximately one half-millicurie of material, a result confirmed in practice.

We have not yet examined in detail the limit of photographic detection, but it is clearly very much lower. For example, a photographic exposure can easily extend over ten or a hundred sweeps; these hundred sweeps take place in about a quarter of an hour, which in many instances would be a reasonable time of exposure. It follows, therefore, that we may hope to photograph patterns corresponding to small fractions of a millicurie.

Experimental Results

Experiments have been carried out with active cobalt, tantalum, and gold wires arranged to form letters of the alphabet, in order to form an estimate of the capabilities of the instrument. Difficulties increase rapidly with increasing penetration of gamma radiation, but even with cobalt-60 we have found it possible to make reasonable visual images of simple sources. Fig. 3 shows the results of experiments with active gold and tantalum wires and illustrates the increased resolution obtained with a 3-mm. as opposed to a 5-mm. diameter aperture. The figure also indicates the degree of resolution obtainable as two parallel line sources are gradually moved relative to each other. It will be noted that the matrix of one hundred spots is adequate for these early experiments, resolution being determined largely by aperture diameter. The photographs represent reasonably the visual image produced on the long-persistent screen oscillograph.

In spite of obvious limitations we have produced with this apparatus recognizable visual and photographic images of radioactive sources, and are continuing with experiments to design and construct apparatus of greater sensitivity and resolution. We are also carrying out experiments with X-ray sources, as it seems that in the X-ray field the apparatus may have considerable application as an image amplifier. Other possibilities include studies of movement of radioactive materials by serial exposure, the formation of stereoscopic images and the direct presentation of the variation of counting-rate over an extended source. [Aug. 2.

THE AMERICAN CHEMICAL SOCIETY AND INTERNATIONAL CHEMISTRY

THOSE who associate the United States with operations carried out with clockwork precision on a gigantic scale would not have been disappointed with the activities of the chemists who attended the Diamond Jubilee of the American Chemical Society in New York during September 3–7 and the Twelfth International Union and International Congress of Pure and Applied Chemistry during September 8–12; the Union completing its activities in Washington, D.C., on September 14–15.

The total enrolment for these events was more than 18,300. Detailed accounts of the proceedings of all three organizations, the technical sessions, lectures, speeches and dinners have already been published in the appropriate journals; indeed, three issues of the American periodical *Chemical and Engineering News* are almost entirely devoted to this subject. There were many interesting features well worthy of comment about these meetings of the largest collection of chemists ever assembled in the world.

While the annual meeting of the American Chemical Society was naturally a domestic affair, yet on this, its seventy-fifth meeting, that Society extended invitations to colleagues overseas and to other kindred domestic societies. There were present forty-one delegates representing societies from thirty-eight nations and seventy-seven delegates from domestic societies. The presentation of scrolls of congratulation took place in the Armoury in New York, where the delegates in their academic costumes were introduced in turn by Prof. Herman Mark to President N. H. Furman, who accepted the scrolls which were then placed by Secretary Alden Emery in a box on the stage. The ceremony on this gigantic scale was extremely impressive. It may not be generally known, but no less than 265 of the younger chemists from forty-five different countries were invited to the United States through the instrumentality of the Economic Cooperation Administration and the Ford Foundation. These had the opportunity of attending the meetings, visiting industrial plants in various sections of the country and of staying a few days in the homes of American scientific men to enable them to get a better appreciation of the American way of life. They were officially welcomed to the meeting by President Furman, Donald Shank of the Institute of International Education, Alden Boyd of the Economic Cooperation Administration and the Ford Foundation, and Alden Emery, the general secretary of the American Chemical Society. This was in addition to the hospitality lavished on the delegates themselves.

The importance of chemistry in the national life is a topic which usually receives attention only from the chemists themselves, but it may be of some importance to other countries to note that at these meetings there was read a letter of welcome from President Truman; an official civic welcome by the City of New York on the steps of the General Post Office; an unveiling of a bronze plaque by Dr. C. Parsons, former secretary of the American Chemical Society, on the wall of the house where the Society was founded seventy-five years ago in Washington Square, the Chelsea of New York; an able address by Governor Driscoll of New Jersey on "Politics in an Age of Science"; a speech by Allan Berkley, the Vice President of the United States, on the "Chemical Problems of the Farmer", in which he reminded his audience of the fact that Thomas Jefferson had regarded chemistry as "the most useful of sciences, big with future discoveries for the utility and safety of the human race". Finally, in Washington an after-dinner speech was given to the delegates of the International Union by Charles Sawyer, U.S. Secretary of Commerce.

The U.S. post office issued ten million commemorative stamps, of which, I believe, more than 2¼ million were sold within the first two days.

The formal meetings and dinners were diffused over the country both by radio and television; a number of the official delegates found several days exposure to 'Kleg' lights rather tiring. It was also significant that the three public speeches addressed to the American Chemical Society all dealt with the future rather than with past achievements; that of President Furman reviewing the present and indicating the future developments within the Society. Dr. J. B. Conant, president of Harvard, chose as his text "A Skeptical Chemist looks into the Crystal Ball", and Dr. Kenneth Mees, of the Kodak Co., dealt with "The View Ahead in Chemistry". These prophets were as optimistic as those who stood before Lars Porsenna.

Both English and American chemical journals and abstracts play a large and important part in world chemistry, and it is evidently desirable that such technical matters as symbols, nomenclature and abbreviations should be as uniform as is possible. This meeting of the American Chemical Society provided a welcome opportunity for those responsible on both sides of the Atlantic to meet and discuss this important matter. Semantics give us no decision between 'sulphur' and 'sulfur' or 'aluminium' and 'aluminum', but the two countries have found it possible to adopt the same symbols and identical logical methods for the necessary chemical shorthand.

As the oldest national chemical society, the president of that of Great Britain was asked to convey the congratulations of the chemical societies invited to this meeting to our hosts; and Arthur B. Lamb, professor emeritus of Harvard, past editor of the *Journal of the American Chemical Society*, was made an honorary life member of the Chemical Society in Great Britain.

In the proceedings of the International Congress, the world-wide ramifications of chemistry were most clearly revealed by the fact that the four official public lectures were given respectively by Prof. V. Deulofeu of Buenos Aires, Prof. K. U. Linderstrøm-Lang of Copenhagen, Dr. E. W. R. Steacie of Ottawa, Canada, and Prof. A. R. Todd of Cambridge in England, while the various committees and commissions of the Union and sections of the Congress were naturally international in character.

In Washington, the Union members were looked after by Dr. E. U. Condon, of the Bureau of Standards, and Dr. D. W. Bronk, of the National Academy of Science. The most important international action completed by the Union consisted in the re-admission of Japan and the admission of Western Germany and New Zealand to the Union. This meeting of the Union terminated the period under the presidency of Prof. H. R. Kruyt. Chemists who have the world interests of chemistry at heart are deeply indebted to one whose wisdom and skill have steered the Union through the difficult post-war period to a position in which it finds itself a living entity and has a real purpose in the complex times in which we live. Prof. Arne Tiselius was unanimously elected as successor, and the next meeting of the Union will be held in Stockholm in 1953. While the sectional meetings, of which there were so many, were managed with the skill born of long practice by the American Chemical Society, it proved too much for the Union, which found that having a congress of pure and applied chemistry on its hands was no joke. Delegates to the Union who thought they had sufficient work to do in the Union itself found that they had, in addition, to participate in many Congress activities. This, indeed, may be the last of the Congresses devoted to all phases of chemical activity. In Stockholm the Congress activities will be restricted to physical chemistry and one or two special topics.

All visitors to the United States are always impressed by the kindness and hospitality of their hosts. Those who attended these conventions will never forget the attentions showered upon them by American individuals, civic authorities, societies and industrial organizations for fourteen memorable days.

Eric K. Rideal

TWELTH INTERNATIONAL CONGRESS OF PURE AND APPLIED CHEMISTRY

THE Twelfth International Congress of Pure and Applied Chemistry was held in New York during September 9–13, immediately following the Diamond Jubilee celebrations of the American Chemical Society. Chemists attending the Congress came from forty-two countries and, of more than nine hundred papers presented, about one-third were by chemists from countries outside the United States. Through the help of the Economic Co-operation Administration and also the Ford Foundation, a number of young chemists from foreign countries were able to attend the Congress and, after its conclusion, were taken on tours of the principal industrial centres of the United States. The Congress was divided into sixteen general sections, but, due to the large number of papers presented, some of these had to be subdivided further. In addition, a general lecture was given each day by a leading chemist (two from Europe, one from North and one from South America) to a combined meeting of all sections.

The first of the general lectures was given by Dr. E. W. R. Steacie, Division of Chemistry, National Research Council of Canada, and was entitled "The Decomposition of Organic Compounds". Taking as examples the thermal decomposition of ethane and the reaction of a methyl radical with an aliphatic hydrocarbon, he reviewed the different approaches and trends over the past few years in the field of gas-phase reaction kinetics. He stressed that, though the original postulates and calculations about free-radical mechanisms have been useful in directing the investigations to date, much more experimental data are needed on a variety of simple reactions. The theoretical approach now involves too many assumptions and approximations, and can only be further advanced when reliable experimental data have been amassed.

Prof. K. U. Linderstrøm-Lang, of the Carlsberg Laboratories, Copenhagen, discussed, in his lecture "Structure and Enzymatic Breakdown of Proteins", the chemistry involved in the conversion of ovalbumin to plakalbumin. He presented evidence showing that when the protein ovalbumin is attacked by a bacterial proteolytic enzyme, the formation of plakalbumin II may correspond to the loss of a hexapeptide unit from the ovalbumin molecule. A reaction also occurs in which plakalbumin I is first formed, corresponding to the removal of a dipeptide (alanyl-alanine) from the original molecule, and then a tetrapeptide is split off more slowly to yield plakalbumin II. It was pointed out that although this comparatively small change in composition, namely, the removal of a peptide of low molecular weight, produces a remarkable change in the crystal form and solubility of the protein, dilatometric studies now reveal that there are other more profound changes in the molecule.

In the third lecture of the series, Prof. A. R. Todd, University of Cambridge, discussed "The Chemistry of the Nucleotides". Reviewing recent work in this field, particularly that of the Cambridge group, Prof. Todd considered the approaches to nucleotide chemistry in relation to nucleic acid structure. Three chemical problems are involved: the structure and synthesis of nucleosides, the phosphorylation of these to give nucleotides, and the method of linkage of dissimilar bodies through the phosphoric acid group. In discussing these, the proof of the β-glycosidic linkage in the nucleosides was described, followed by an account of the use of dibenzyl-chlorophosphonate as a mild phosphorylating agent. The uncertainty of the location of the phosphate group on either the 2- or 3-position of ribose in the nucleotides was explained by the possible cyclization of the phosphate group across these positions. This would also account for the alkali-instability of ribonucleic acid and for the isolation of isomeric adenylic acids by Carter and Cohn. In the light of the known chemical properties of the nucleotides, particularly their behaviour to acid and alkali, possible structures of ribo- and deoxyribo-nucleic acids were considered.

In the final lecture of the Congress, Prof. V. Deulofeu, National University of Buenos Aires, gave a short talk on "The Chemistry of some South American Plant Products". This dealt with the chemistry of the alkaloids and flavonols found in various plants and bushes in that region. The structure of γ-fagaradine and the other alkaloids from the plant *Fagara coco* was discussed by considering their relation to dictamine. The theoretical basis for their various reactions was considered, and the synthesis of analogues of α-fagarine with comparable pharmacological activity was described. The three Argentine species of *Erythrina* examined contain two main alkaloid fractions, one group being the free bases (for example, erythramine, erythratine), while the others are glycosidically bound and only liberated in extractable form by acid hydrolysis (for example, erysotrine, erysovine). The structure and inter-relation of these compounds and their relation to the parent base erythradine were discussed.

Several of the larger sections of the Congress organized their programmes to include symposia on particular aspects of current interest. Thus the Medicinal Chemistry Section, for example, held symposia on antibiotics, tuberculosis and cancer. In these the stress fell mainly on the chemotherapeutic approach, several papers being presented on the new antibiotic 'viomycin', derived from *Actinomyces vinaceus*, and on the use of compounds of the thiosemicarbazone group against tuberculosis and of the derivatives of ethyleneimine against cancer. The Biological Chemistry Section held a two-day symposium on proteins and amino-acids, and also symposia on nucleic acids, enzymes and microbiological chemistry. The sections entitled Plant Cell-wall Constituents, Air and Stream Pollution, Pesticides, etc., held symposia on specific aspects in those fields. The Physical and Inorganic Chemistry Section and the Organic Chemistry Section arranged very large general programmes covering many aspects.

The field of chemistry has now become so vast that for future international meetings it seems it will be necessary to subdivide the Congress into independent units. Accordingly, the next International Congress of Chemistry, to be held at Stockholm in 1953, in conjunction with a meeting of the International Union of Pure and Applied Chemistry, will be restricted solely to the Physical Chemistry Section.

D. HAMER

OBITUARIES

Mr. James Baddiley

MR. JAMES BADDILEY, who died in hospital on September 26, was one of the outstanding leaders in the renaissance of the dyestuffs industry in Great Britain. He was born in Yorkshire on July 15, 1885, and educated at Bradford Grammar School, whence he went to the University of Leeds and graduated with first-class honours in 1907. He then worked for two years with Prof. A. G. Green in the Clothworkers' Research Laboratory, and during this period published, with Green, in the *Transactions of the Chemical Society*, a paper in a series on colouring matters of the stilbene group, dealing with the action of caustic alkali on derivatives of *p*-nitrotoluene. In 1909 he joined Levinstein's, Ltd., at Blackley as research chemist, and in the next five years he worked chiefly on azo dyestuffs and intermediates, work which issued in twelve British patents with Dr. H. Levinstein as co-inventor.

By the outbreak of war in 1914, Mr. Baddiley had already established his reputation as a research chemist, and he quickly became the head of the Technical Research Department at Blackley, of which he retained charge when the British Dyestuffs Corporation was formed. In 1925, Prof. A. G. Green having meanwhile resigned his post as director of research, Baddiley became manager of the Research Department. In 1930, the British Dyestuffs Corporation having become part of Imperial Chemical Industries, Ltd., Mr. Baddiley became a delegate director, and joint technical manager of the Dyestuffs Group, remaining director in charge of research until his retirement in 1947.

Although only one scientific paper stands in his name, he was cited as co-inventor on some sixty British patent specifications. When the Board of Trade Dyestuffs Development Committee issued its first report in August 1920, it referred to five outstanding developments in dyestuffs chemistry, three of which were British discoveries, and with two of these Mr. Baddiley was associated. One was his discovery in 1922, with the late Mr. A. Shepherdson, of the valuable dyeing properties of dispersions of unsulphonated amino derivatives of anthraquinone for acetate rayon; the other was his contribution to the use of dispersions of azo dyestuffs for the same purpose. Both discoveries considerably assisted the development of the use of cellulose acetate as a textile fibre. A further discovery, also listed by the Dyestuffs Development Committee in its report, with which Mr. Baddiley was associated, was that of a special range of azo dyes giving level shades on the 'irregular' viscose rayon which at that time was frequently encountered. Mr. Baddiley's services to the industry were recognized in February 1939 by the award to him of the Perkin Medal of the Society of Dyers and Colourists. This, the premier award in the field of dyes and their application and textile chemical technology, was awarded "in recognition of his national services for the renaissance of the British dyestuffs industry through many important investigations in the field of colouring matters conducted or directed by him".

Mr. Baddiley retained to the end his interest in and enthusiasm for dyestuffs technology and organic chemistry, remaining a keen student of the literature. Only his last illness prevented him from presenting a paper he had prepared for the Society of Dyers and Colourists' conference last September. Outside chemistry his chief interests were in his family and, in early life, walking in the Peak district, the Lake district, or his native county, of the fells and inns of which he had an extensive knowledge. He came of farming stock and had also a keen interest in agriculture.

On the research side at least, no one else can have played a part in the renaissance of the British dyestuffs industry in any way comparable with that of Mr. Baddiley; but some who knew him may remember him as much as an inspirer and encourager of others as for his own technical achievements. A wide circle of colleagues who regret the passing of one who earned their respect and affection will extend their sympathy to his widow and children.

Dr. A. L. Green

We regret to report that Dr. Alfred Leonard Green, who was officer in charge of the Ionospheric Prediction Service of the Commonwealth Observatory, Mount Stromlo, Canberra, died in Sydney on August 29, after a trying illness. Dr. Green was born in 1905 in London and educated at Bancrofts School, Essex, from which he proceeded to King's College, University of London. In 1927 he became assistant to Sir Edward Appleton, and was engaged on investigations on the ionosphere, and in 1930 he joined the staff of the Radio Research Board in Sydney. He at once made an investigation of the polarization of down-coming waves in the southern hemisphere and found that it was opposite to that in the northern, thus carrying out a crucial test of the magneto-ionic theory. Dr. Green continued with the Radio Research Board, for which he conducted a number of important investigations, until 1935, when he joined Amalgamated Wireless (Australasia), Ltd., becoming chief of the Research Laboratories. In 1947 he became officer in charge of the Ionospheric Prediction Service at the Commonwealth Observatory, and introduced considerable improvement into the methods of forecasting. He was about to organize a programme of experimental work in the various ionospheric stations operated by the Service, the staff of which he had recruited, when he was incapacitated by his last illness. Green was a Ph.D. and later D.Sc. of the University of London. He is survived by a widow.

R. v. d. R. Woolley

NEWS and VIEWS

Nobel Prize for Medicine for 1951: Dr. Max Theiler

Dr. Max Theiler, who has been awarded the Nobel Prize for Medicine for 1951, was born in South Africa in 1899, a son of Sir Arnold Theiler, whose work in veterinary problems in Africa is widely recognized. Dr. Max Theiler received his medical education at St. Thomas's Hospital, London, and graduated in 1919. Upon completion of a course at the London School of Tropical Medicine, he accepted a post at Harvard University in the Department of Tropical Medicine, where his work ultimately led to the demonstration of the susceptibility of white mice to intra-cerebral inoculation of yellow fever virus. This made possible for the first time work with yellow fever virus in a small and inexpensive animal. Dr. Theiler eventually developed the mouse protection test which has become one of the principal tools in yellow fever epidemiology. It was after Dr. Theiler had moved to the International Health Division of the Rockefeller Foundation in New York that the historic discovery of the innocuous nature of the *17 D* sub-culture of the well-known Asibi strain of yellow fever virus was made. This is the strain which served for the major portion of the millions of yellow fever immunizations given during the past decade. If further evidence of Max Theiler's careful workmanship is necessary, this is furnished by his discovery of the interesting murine encephalomyelitis virus which bears his name.

Dr. Theiler is certainly one of the most modest of men. He rarely attends scientific meetings, despite an extremely affable and friendly nature, and in his laboratory he seldom presents a picture of the intensity which is customarily expected of the scientific investigator. This easy-going approach to his work, however, disguises very effectively the enormous amount of thinking which lies behind each and every one of his experiments. He is most characteristically found sitting at ease in his laboratory, examining and re-examining the results of the experiments being conducted by his team of very competent technicians, whom he has himself trained. While he will no doubt be greatly pleased by the award of the Nobel Prize, it is unlikely that the very human Max Theiler will be changed one whit by it.

Grande Médaille Osmond: Prof. E. N. da C. Andrade, F.R.S.

On October 26, during the autumn conference of the Société Française de Métallurgie, Prof. E. N. da C. Andrade was presented with the Grande Médaille Osmond, a premier award in the field of metallurgical science. This honour was instituted in 1949 on the occasion of the centenary celebrations of the birth of Floris Osmond, a pioneer in metallography, and is awarded—to translate literally the conditions laid down—"without condition of nationality, in principle every two years, to a metallographer whose scientific works have had important consequences for metallurgy and the study of metals, so as to constitute a crowning award to work judged of first importance in metallurgical science". The first award was made to the distinguished Swedish man of science, Prof. Carl Benedicks. Present-day knowledge of deformation processes in metals owes much to the painstaking work and penetrating observations of Prof. Andrade. His early experiments on the creep of metals led to the relationship now generally known as the 'Andrade creep law', and to the recognition of the fact that at least two physically distinguishable processes play a part in creep phenomena. He was among the earliest investigators to prepare single crystals of metals and study their deformation. Characteristically, he devised methods for the preparation of the more difficult materials and elucidated their modes of deformation. The methods he devised, both for preparation and testing of the materials, have found widespread use in laboratories all over the world. More recently, his work has established the importance of the role of the surface in the mechanical behaviour of both polycrystalline and monocrystalline metals. Already, as with many other phenomena to which he first directed attention, these observations have been pursued by other workers with fruitful results. This work, for which the Médaille Osmond has been awarded, constitutes, of course, but a part of Prof. Andrade's contributions to science as a whole; his original work has ranged over the whole field of physics, while he has yet found time to interpret science to the layman and make significant contributions to the literature of the history of science.

Mechanical Engineering Research Organization : Dr. D. G. Sopwith

DR. D. G. SOPWITH, until recently superintendent of the Engineering Division, National Physical Laboratory, Teddington, has been appointed director of mechanical engineering research in the Department of Scientific and Industrial Research in succession to the late Dr. G. A. Hankins. Since the death of Dr. Hankins in November last year, Dr. Sopwith has been acting director. He will now take complete charge of the new Mechanical Engineering Research Organization, the laboratories of which at East Kilbride, near Glasgow, are already partially built (see p. 779). Dr. Sopwith, who is forty-five years of age, was born in London and was educated at Manchester Grammar School and the University of Manchester. At the University he obtained a Whitworth Scholarship and graduated with first-class honours in mechanical engineering in 1928. He then joined the staff of the National Physical Laboratory, Engineering Division, becoming superintendent of the Division in 1948. He has published many papers on a wide range of subjects, including the design and causes of failures of engineering components, and others on chains and lifting gear, fatigue, helical compression springs, screw threads, the penetration of armour plate, and breech mechanisms.

British Caribbean Meteorological Service : Mr. W. A. Grinsted

MR. W. A. GRINSTED, director of the newly established British Caribbean Meteorological Service, has recently taken up his appointment at the headquarters of the Service in Trinidad. Mr. Grinsted joined the Meteorological Office in 1920 and was appointed to the British East African Meteorological Service in 1934. In 1942 he was made assistant director of what, in 1948, was to become the Meteorological Department of the East Africa High Commission. Since the Second World War, meteorological services in the Caribbean have been operated by the Air Ministry. The establishment of the new Service was recommended by a conference which met in Trinidad in January, at which it was decided that the Government of Trinidad and Tobago would administer the scheme on behalf of the other Governments concerned, though the director would have direct contact with the other Governments. The cost of the new Service will be met by these Governments, assisted by grants from Great Britain from Colonial Development and Welfare Act funds and by a contribution from the Ministry of Civil Aviation.

Leadership Training in the Universities

SIR WALTER MOBERLY'S Walker Trust Lecture on Leadership, which he delivered to the University of St. Andrews on February 13, and which is now published (London : Oxf. Univ. Press. 2*s*. 6*d*.), was an examination of the grounds on which the universities' traditional task of leadership is disclaimed to-day. Sir Walter suggested that there is no longer a keen demand for the qualities fostered by a traditional university education, and that for the universities to aim deliberately at producing numbers of a ruling class is wrong in principle as well as impracticable. Again, even if education for leadership were a desirable aim in itself, we are now asked whether, in the present cultural situation, it is possible for the universities to impart it or for students to acquire it. It is urged by Mr. T. S. Eliot that we are sacrificing quality to quantity and that the training of an élite of gifted individuals cannot entirely compensate for the disappearance of an upper class. Finally, the disappearance of any ground-pattern of common belief and behaviour is a crippling handicap. Sir Walter concedes the weight of these objections, but maintains that education for social responsibility is nevertheless still a legitimate and essential task of the universities. Whenever the management of affairs or the guidance of public opinion is left to persons or groups who are not really respected, the life of the community suffers. "The imaginative understanding which illuminates facts" is the one quality most urgently needed in statesmen and all leaders of opinion to-day. If the universities are still to educate for leadership, but for leadership of a more novel kind, Sir Walter suggests first that the family life of the university to-day needs special emphasis. Next, members of a university community should go out of their way to mix with those whose background, professional interest, opinions, and perhaps nationality, differ from their own ; and thirdly, they should seek to avoid the danger of narrowness, for example, by everyone examining the tacit assumptions of his own subject of study and by thinking strenuously about the great issues of right and wrong, liberty and order, faith and scepticism.

Royal Meteorological Society : First Annual Dinner

THE Royal Meteorological Society celebrated last year its centenary, and this year the new session commenced with the inauguration of the Society's first annual dinner, which was held on October 17 in London. The Society's new president, Sir Charles Normand, welcomed the guest of honour, Sir John Slessor, chief of Air Staff, who in proposing the toast of the Society gave many important instances of the use of meteorology as a weapon of war, particularly in aviation. Sir John pointed out, however, that aviation is equally important to meteorology. The Meteorological Research Flight at Farnborough, for which the R.A.F. supplies the aircrews and the Meteorological Office the scientific observers, has rendered unique service to meteorological research. In responding, the retiring president of the Society, Sir Robert Watson-Watt, drew a careful distinction between the Royal Meteorological Society and the Meteorological Office. Sir Robert commented on the disparity in the *per capita* expenditure in Great Britain on meteorology and that in the United States, which is greater in the ratio of 17 : 10. An expansion of the meteorological service would be of great value to Britain, not only to aviation but also in many other directions, and notably to agriculture.

The Wood Pigeon in Britain

FOR many years it has been recognized that the wood pigeon in Britain is harmful to agriculture, and varied attempts have been made to prevent its depredations. With the coming of the Second World War, renewed interest was taken in the protection of growing crops and in reducing the number of wood pigeons. In due course the British Trust for Ornithology received a grant from the Agricultural Research Council for research on the biology and control of this species. During the war years the Wood Pigeon Investigation, which was given facilities for working at the Edward Grey Institute of Field Ornithology, Oxford, was naturally preoccupied with the problem of control, and research on the habits of the species was built up on this central theme. For example, a survey of nests was undertaken with the object of discovering whether the pigeons could be controlled in their breeding quarters; plumage was studied to obtain a clue to the migration problem; a knowledge of the relative density of the population was obviously desirable; and a similar knowledge of the feeding habits and feeding grounds was essential for the main purpose in view. The work on control has now been closed and it is possible to knit together the results of research on the biological side, which together form a study of the effect of human activities on one species of bird. Although the wood pigeon is as wild and unapproachable as any member of the British fauna, it would be difficult to name any animal the life-history of which is more closely interwoven with that of man. This life-history has been described by M. K. Colquhoun in an account which should be of interest not only to ecologists but also to those associated with the practice of agriculture and forestry (Agricultural Research Council. Report Series No. 10. London: H.M.S.O. 3*s*. net).

Material Culture of a Micronesian Atoll

Kapingamarangi, an atoll south of the Caroline Islands and just north of the equator, was chosen as the field for an expedition to Micronesia, since it was known to be inhabited by a Polynesian stock. The people are taller and more robust than the Micronesians, with typically Polynesian brown skin and wavy or curly hair, and they are friendly and hospitable. There are thirty-three islets on the reef around the central lagoon, with a population of more than five hundred. This atoll, then, formed a highly compact area for an intensive survey—and how intensive it was is shown by an account of "Material Culture of Kapingamarangi", by Te Rangi Hiroa (Peter H. Buck) (Bernice P. Bishop Museum, Honolulu; Bull. 200; pp. 291; 1951). The field has been covered minutely, and the profuse illustrations are of high merit; in fact, the whole publication serves as a model of how such a survey should be presented. It is interesting to find a community nowadays living such a balanced life. They are isolated, but not entirely so; they are self-supporting, healthy and happy, and what outside culture—social and material—they now desire can be supplied by their outside contacts. Let us hope that this balance is not upset by so-called civilization.

Library Catalogue of the Timber Development Association

The Timber Development Association, Ltd., has at its headquarters (21 College Hill, London, E.C.1) a library containing more than a thousand books treating of matters of importance in the timber and wood-working industries, and so forth. The titles of these books are given in the "Library Catalogue" (pp. 54), the third edition of which appeared in April 1950 and was reprinted in February 1951. The catalogue does not include any of the many brochures, pamphlets, and trade catalogues which may be inspected at the headquarters. The catalogue is drawn up on the usual lines, and forms a valuable aid to those who are associated with timber development.

World Power Conference: Annual Report for 1950

The annual report of the World Power Conference for 1950 (pp. 22; London: World Power Conference, 1951) records the admission of Iceland and Israel to membership at the 1950 meeting of the International Executive Council, and national committees have been formed in both countries. A brief chronicle of the Fourth World Power Conference is appended to the report, and the transactions of the Conference are being prepared for publication. The International Executive Committee protested unsuccessfully against the decision of the Economic and Social Council of the United Nations to transfer the World Power Conference from the list of organizations having category-*B* consultative status to the Secretary-General's Register. A list of publications as well as the statement of accounts is appended to the report, the income and expenditure account showing a deficit of £261 on the year.

"Runs in a Sequence of Observations"

Referring to the communication under this title published in *Nature* of September 29, p. 557, Prof. P. V. Krishna Iyer writes: "The determinantal difference equation should be read as follows: The difference equation reduces to a determinant of the k^2 order given by

$$\| A_{rs} \| \varphi(m-2) = 0,$$

where A_{rs} is a $k \times k$ matrix such that when $r \neq s$, all rows excepting the sth row are zero, the sth row being $[-p_{rt} \; -p_{rt} \; . \; . \; . \; -p_{rt}]$. When $r = s$, the rth row is $[-p_{rt} \; -p_{rt} \; . \; . \; . \; (E-p_r) \; . \; . \; . \; -p_{rt}]$, the diagonal elements are $[E \; E \; E \; . \; . \; . \; E-p_r) \; . \; . \; . \; E]$, all the other terms being zero".

University of London

The following announcements have been made by the University of London. Mr. A. G. Smith has been appointed to the University readership in applied thermodynamics tenable at the Imperial College of Science and Technology. Doctorates have been conferred as follows: *D.Sc.*, J. G. Boswell (King's College), Miss M. S. Leslie (Bedford College), Miss L. M. Pickford (University College) and F. L. Warren (Imperial College of Science and Technology); *D.Sc.(Eng.)*, F. W. Preston (external student).

Announcements

Mr. Ben Smith, national organizer of the Association of Scientific Workers, has been appointed general secretary of the Association in succession to Mr. T. Ainley.

The new laboratories of the British Food Manufacturing Industries Research Association at Randalls Road, Leatherhead, will be opened by Lady Engledow on November 8.

A British Commonwealth Scientific Official Conference will be held in Australia in 1952. This is the first time the Conference has been held outside the United Kingdom; the last Conference met in London in 1946. The Conference will open in Canberra on February 18, and will close in Melbourne on March 7; the formal sessions will be broken by visits to enable delegates to study problems of Australian development. Local arrangements for the Conference are in the hands of the Commonwealth Scientific and Industrial Research Organization, 314 Albert Street, East Melbourne.

REPRODUCTIVE ORGANS OF NEAR-TERM AND NEW-BORN SEALS

By Prof. E. C. AMOROSO
Physiology Department, Royal Veterinary College, London, N.W.1

Dr. R. J. HARRISON
Anatomy Department, London Hospital Medical College, London, E.1

Dr. L. HARRISON MATTHEWS
Zoological Society of London, Regent's Park, London, N.W.8

AND

Dr. I. W. ROWLANDS
Wellcome Veterinary Research Station, Frant, and Institute of Animal Physiology, Babraham, Camb.

THERE is convincing physiological evidence indicating that, in several species of mammals, including man, horse and donkey, œstrogens and progesterone are elaborated by extra-ovarian tissues[1,2]. It is generally believed that the placenta represents the new source, though the available evidence falls short of finality[3,4].

The genital organs of the human infant at birth and of the fœtal foal show characteristic gross and microscopic alterations, and it is evident that they have been exposed to strong and physiologically effective stimulation from endocrine substances. Histological and biochemical investigations, fully presented for man by Fraenkel and Papanicolaou[5], and by Dobszay[6], and for the horse by Cole, Hart, Lyons and Catchpole[7], and by Amoroso and Rowlands[8], have revealed certain details of these transitory phenomena. On the other hand, data regarding the histological structure of the reproductive tract in mature fœtuses or in the new-born of other species have not been reported in sufficient detail to enable comparisons to be made, or to assess the endocrine status of the extra-ovarian tissues that may be involved. In the cat, for example, the uterine glands of the new-born kitten are stated to be active; but this activity ceases soon after birth[9], while in mature fœtuses of the African elephant, Perry[10] has described a pronounced enlargement of the gonads which regresses soon after delivery.

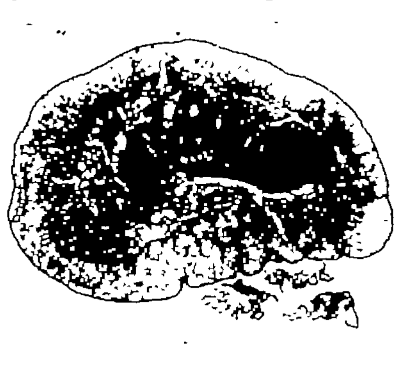
We have recently examined the reproductive organs of a number of near-term and full-term seal fœtuses, and new-born and recently born seal pups of both sexes. In several instances the maternal ovaries and portions of the maternal genital tracts have been sectioned. Material from different species (*Halichoerus grypus*, *Phoca vitulina* and *Callorhinus ursinus*, and three species of Antarctic seals, *Leptonychotes weddelli*, *Lobodon carcinophaga* and *Hydrurga leptonyx*) has been examined. The gross and microscopic findings are essentially similar, although not yet confirmed at every stage, for each species. We find a remarkable enlargement of the gonads of all near-term fœtuses and new-born pups, an observation already made by one of us[11] in *P. vitulina*. A characteristic hypertrophy and engorgement of the uterus, changes in the vaginal epithelium and a large plug of tenacious mucus in the anterior vagina are associated with this phenomenon.

The ovaries of near-term and new-born seals present a picture which is remarkably different from the appearances seen some weeks after birth[11]. The ovaries are strikingly enlarged—larger, in fact, than those of the mother—but are devoid of follicles in a stage of development more advanced than those lined by a single layer of follicular epithelium. The large size is due to an especially developed proliferation of interstitial cells which make up the bulk of the organ. At birth the ovaries weigh 32–36 gm. and those of the mother weigh 25–28 gm.

In the ovary of the new-born, the primordial follicles lie immediately below the tunica albuginea and tend to be arranged in clusters in the neighbourhood of sub-surface crypts of germinal epithelium, which are present at irregular intervals in the cortical zone[12,13]. The remainder of the organ consists mainly of loosely arranged, well-vascularized interstitial tissue. The interstitial cells are large, oval or polyhedral, and have abundant eosinophilic cytoplasm. In the majority of cells, the nucleus is eccentrically placed and is large and vesicular; but it is occasionally shrunken and pyknotic.

Involution of the ovaries begins three or four days after delivery and is well advanced by the second week (see illustration). The ovaries weigh 8–10 gm. during the second week, and 2–4 gm. when involution is completed. During involution the interstitial cells undergo a lipid transformation, shrink considerably and become densely packed. The majority of the nuclei are now shrunken and pyknotic.

The uterus of new-born seals is relatively large and congested, and, as in the human neonate[5], the cervical canal is more definitely patent during the neo-natal period than immediately thereafter. Macroscopically the uterine horns resemble those of the bitch when in œstrus. In sections, the uterine mucosa is thickened and the uterine epithelium is frequently several layers thick. The uterine glands are numerous,



Photograph of longitudinal sections through the greatest diameter of (above) full-term fœtal and (below) approximately week-old phocid ovaries. Natural size enlarged and extend in coils to the base of the mucosa. There is definite evidence of active secretion. A week after birth the uterus has started to shrink; the uterine epithelium is single-layered, the glands are smaller and their cells heavily vacuolated, and there are only traces of secretion.

The vagina contains a large coherent plug of thick mucus lying immediately caudal to the cervix uteri. During involution, the amount of mucus in the vagina decreases and the viscosity is lowered. Histologically, a multi-layered hypertrophy of the epithelium of the posterior vagina prevails; but anteriorly it is converted into a mucus-secreting type, frequently with a superficial layer of tall columnar cells, and containing occasional, large, darkly staining, granular cells, the nature of which has not yet been determined. The secretions which accumulate in the lumen of the vagina contain desquamated epithelial cells in addition to red and white corpuscles. Usually the extravasated blood in the vagina is small and insufficient to colour the mucus, but occasionally—and especially during involution—it may accumulate in such quantities to stain the secretions a dark red colour. About a week after birth the vaginal epithelium is thinner, and in many places has the appearance of a transitional epithelium.

In male pups the gonads follow a similar curve of growth and decline as do the ovaries, and in the new-born weigh 34–40 gm. The testes are covered by a well-defined tunica albuginea which varies in thickness from 600 to 800 µ. They contain large islands of interstitial tissue, between which are found numerous, convoluted seminiferous tubules that contain an occasional spermatocyte. The majority of the tubules are patent, but some are solid. On an average, the tubules measure about 60 µ in diameter.

Our observations on the maternal ovaries just before, during and after parturition confirm those of Enders, Pearson and Pearson[14]. The ovary containing the heavily vacuolated corpus luteum of pregnancy possesses very few, small atretic follicles; the other contains numerous healthy follicles 0·2–4 mm. in diameter and frequently, as in one cow which died during labour, one or more follicles up to 12 mm. in diameter. It is one of these larger follicles which is probably destined to rupture at the post-parturient ovulation some three to eight days after delivery.

The modifications of the reproductive organs of the seal which normally prevail at birth parallel in almost every respect those described in the new-born infant and the fœtal foal. But whereas the changes in the uterus and vagina of the aforementioned species can be ascribed almost entirely to circulating œstrogens, the occurrence of coiled endometrial glands and vaginal mucification in the seal suggests that progesterone is acting upon an œstrogen-primed genital tract. It is probable from the appearances of the maternal ovaries in the seal just before and at birth that they are at least a contributory source of circulating œstrogens, and possibly of progesterone. The extent to which gonadal enlargement can be attributed to the same cause is more difficult to assess. The reaction of the interstitial cells in the gonads resembles a response to the luteinizing fraction of the anterior pituitary; and unless we can assume that endocrine substances having the property of chorionic gonadotrophin are secreted by the cytotrophoblast of the seal's placenta (as has been demonstrated for man), then the remarkable changes in the ovary of the seal at birth might be ascribed to the presence of circulating œstrogens or to changes in the kind and quantity of gonadotrophic hormones secreted by the fœtal pituitary. [June 26.

CHEMISTRY OF THE OXIDATIVE METABOLISM OF CERTAIN AROMATIC COMPOUNDS BY MICRO-ORGANISMS

By Dr. W. CHARLES EVANS and B. S. W. SMITH
Agricultural Biochemistry Section, University College of Wales

AND

Prof. R. P. LINSTEAD, C.B.E., F.R.S., and
Dr. J. A. ELVIDGE
Department of Organic Chemistry, Imperial College of Science and Technology

SEVERAL types of micro-organisms, classified into the following six families, Coccaceæ, Mycobacteriaceæ, Bacteriaceæ, Pseudomonadaceæ, Spirillaceæ and Bacillaceæ, are known[1], which grow in a simple mineral salt medium with an aromatic compound as the sole source of organic carbon. During growth, the benzene ring undergoes fission, the compounds formed being utilized in the diverse processes associated with cell metabolism. Such organisms have been isolated from soil, sewage and mammalian fæces, and are widely distributed in Nature. Indeed, the biological function of these micro-organisms by virtue of this property may be regarded as an essential step in the 'carbon' cycle. Their use as industrial scavengers is common, since percolation of phenolic waste-products through sewage beds provides a cheap method of detoxicating aromatic substances potentially harmful to aquatic life. Useful reviews by ZoBell[2] on the bacteriological aspects of this phenomenon have been published.

The biochemistry of bacterial aromatic ring fission has been investigated by the application of two entirely distinct methods of approach, and has been reviewed by Happold[3]. These are the traditional one of attempting the isolation of intermediates from growing cultures, mainly by Evans and Happold and their collaborators, and, secondly, through the utilization of the technique of 'simultaneous' or 'successive' adaptation by Stanier. Recently, cell-free enzyme preparations from bacteria which have grown on one aromatic substrate, and therefore

possessing the adaptive enzyme pattern for its metabolism, have yielded important new information concerning the chemical steps in this metabolic pathway.

Table 1 summarizes the knowledge gained by several investigators concerning the bacterial 'aromatic fission' type of metabolism of some biochemically important substances.

It is now generally recognized as desirable that before any presumed intermediate is finally accepted as participating, it must, first, obey the criteria of simultaneous adaptation and, secondly, have been identified chemically, either from the culture or as a product of reaction of an enzyme preparation made from the adapted cells acting on a preceding member in the reaction chain. Some comment on the unified scheme presented in Table 1 is useful at this stage.

Pathways (1), (2), (3). Using *Vibrio* 01, Evans and Happold[4] isolated catechol from a culture growing on phenol media; with *p*-hydroxybenzoic acid as initial substrate, Evans[5] identified protocatechuic acid as one of the products. The course of the metabolism of benzoic acid proved more difficult to determine, since none of the monohydroxybenzoic acids appeared to be formed, neither did the three isomers obey the criteria of simultaneous adaptation. Stanier[6] provided evidence, by the latter technique, that the metabolic pathways of benzoic and *p*-hydroxybenzoic acids with his *Pseudomonas fluorescens* organism are initially separate and distinct. Almost simultaneously, Evans, Parr and Evans[7] isolated catechol from a benzoate culture of *Vibrio* 01. No known intermediate has been found to take part between these two compounds, and it appears probable that these organisms produce catechol from benzoic acid in a single oxidative reaction.

In the original biochemical work on phenol breakdown, Evans and Happold[4] and Evans[5] detected the transient formation of a keto-acid which gave a positive Rothera and Gerhart test, but which was not identical with aceto-acetic acid. This elusive intermediate was finally characterized by Kilby[8] as β-ketoadipic acid. Afterwards it was shown by Evans, Parr and Evans[9] that protocatechuic acid also gives rise to β-ketoadipic acid after ring cleavage. Whether β-ketoadipic acid is the immediate product of ring opening in pathways (1), (2) and (3) remained obscure until quite recently.

Pathways (5), (6), (7), (8). That mandelic acid is metabolized through benzoic acid by *Pseudomonas fluorescens* was established, through simultaneous adaptation, by Stanier[6]. Recently, Evans and B. S. W. Smith[10] have shown that *p*-cresol gives rise to *p*-hydroxybenzoic acid by its isolation from culture. Evidence has also been obtained by the latter workers indicating that phenylalanine and tyrosine undergo side-chain oxidation to *p*-hydroxybenzoic acid prior to ring cleavage.

Pathway (4). Suda, Hayaishi and Oda[11] studied the adaptive behaviour of *Pseudomonas* spp. in tryptophane metabolism. One of the significant results of their work was that this occurs through kynurenine and anthranilic acid, to catechol, this latter compound being further metabolized by ring fission. In fact, Hayaishi and Hashimoto[12] succeeded in purifying an enzyme system from these *Pseudomonas* spp. which they termed 'pyrocatecase', able to convert catechol to what was believed to be *cis-cis*-muconic acid. When, however, the substance isolated was tested by Stanier and Hayaishi[13] with a crude enzyme preparation which catalyses the reaction

$$\text{catechol} + O_2 + H_2O \rightarrow \beta\text{-ketoadipic acid},$$

it was found incapable of giving the keto-acid, a fact which excluded it from being a true intermediate in this reaction. The position, therefore, remained for a time rather puzzling.

At this stage the investigations of Elvidge, Linstead, Sims and Orkin[14] on the stereochemistry of the muconic acids threw light on the microbiological problem. These workers isolated a new *cis-trans*-muconic acid from the alkali-catalysed isomerization of a related unsaturated lactone. The new acid (m.p. 184° C.) resembled very closely the *cis-cis*-muconic acid which can be prepared by the chemical oxidation of phenol[15]. When the *cis-cis*-acid is merely boiled with water, it is inverted into the new *cis-trans*-isomeride. This means that many samples of '*cis-cis*'-acid used by previous workers must have been inverted by the usual processes of purification. Methods of identifying the two stereoisomerides and the proof of their configuration have been described[14]. It may be added that the configurations have recently been confirmed by semi-hydrogenation experiments (in which the *cis-cis*-muconic acid gives only *cis*-Δ^{α}-dihydro-muconic acid, whereas the *cis-trans*-acid gives both *cis*- and *trans*-Δ^{α}-dihydro-muconic acids)[16].

A difference between the acids is also clearly shown in the microbiological work as follows. The three muconic acids were examined as substrates by Evans and B. S. W. Smith[17]. These experiments showed that the bacterial enzymes which convert catechol to β-ketoadipic acid do so through the intermediate formation of the *cis-cis*-form of muconic acid (I). The enzymes show a rigid biological specificity in this respect, being without action on the other two geometrical isomers. These facts explain why the muconic acid isolated by Hayaishi and Hashimoto was not converted into β-ketoadipic acid by the appropriate enzyme system. In their process of isolation, isomerization of the *cis-cis*-muconic acid to the *cis-trans* form must have occurred. That this explanation is correct has been confirmed by Stanier and Hayaishi[13]. *cis-cis*-Muconic acid, however, does not appear to participate in pathway (3), but Stanier[18] has provided evidence of the formation of a tricarboxylic acid, possibly β-carboxy-muconic acid, in this pathway.

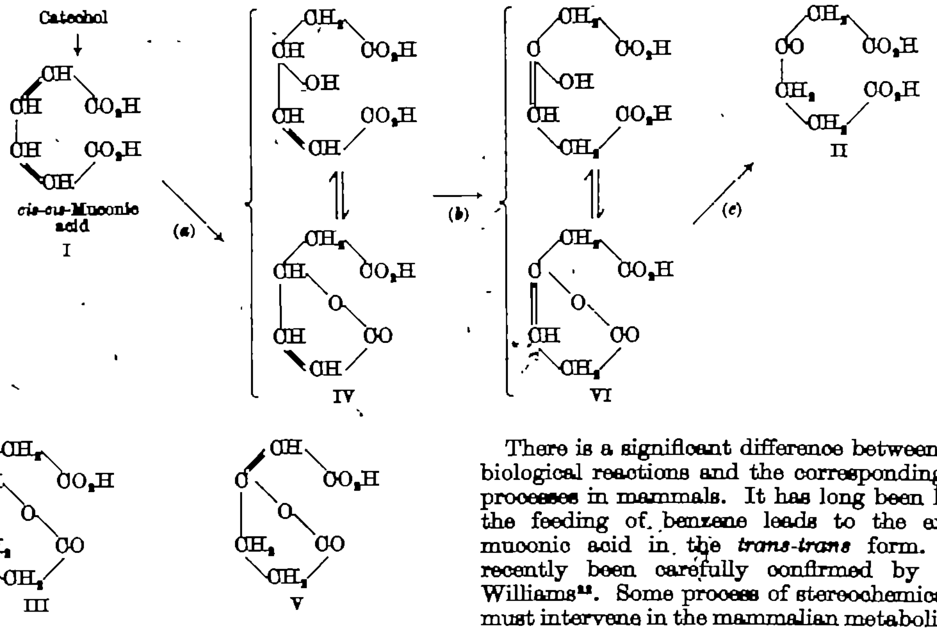
Attention has now been given to the possible intermediate stages between *cis-cis*-muconic acid (I) and β-ketoadipic acid (II), which is the common intermediary metabolite of the various substrates (1)–(8).

Using an enzyme preparation from catechol-adapted cells of *Vibrio* 01 and *Pseudomonas fluorescens* strains, it was first demonstrated manometrically that this reaction (I) → (II) proceeds quantitatively without the participation of molecular oxygen (the β-ketoadipic acid produced was estimated by measuring the carbon dioxide formed on decarboxylation with aniline citrate). This meant that no change was likely to occur in the oxidation-level of the metabolites, and this was confirmed by experiments in which adipic acid, and the saturated lactone (III) equivalent to β-hydroxyadipic acid, were incubated with the cell-free enzyme system. The formation of β-ketoadipic acid was tested for by the Rothera reaction and the ferric chloride reaction. None was formed.

TABLE 2. ACTION OF THE AROMATIC RING-SPLITTING ENZYME SYSTEM FROM CATECHOL-GROWN CELLS ON POSSIBLE INTERMEDIATES IN THE PRODUCTION OF β-KETOADIPIC ACID

Substrate (50 mgm. in 7 ml. M/20 phosphate buffer, adjusted to *p*H 7; 3 ml. enzyme solution)	Production of β-keto-adipic acid after:		
	15 min.	30 min.	60 min.
Catechol	+	+	+++
cis-cis-Muconic acid	+	++	++++
cis-trans-Muconic acid	–	–	–
trans-trans-Muconic acid	–	–	–
Protocatechuic acid	–	–	–
γ-Carboxymethyl-Δ^{α}-butenolide (IV)	++	+++	++++
γ-Carboxymethylenebutanolide (V)	–	–	–
Dihydro-lactonic acid (III)	–	–	–
Adipic acid	–	–	–

Table 3.—Mechanism of the Conversion of *cis-cis*-Muconic Acid to β-Ketoadipic Acid by the Aromatic Ring-splitting Enzyme System from Catechol-grown Bacterial Cells



β-Ketoadipic acid differs from muconic acid by the elements of a molecule of water. Addition of water to *cis-cis*-muconic acid would be expected to yield the β-hydroxy acid which could readily cyclize to the unsaturated lactonic acid, γ-carboxymethyl-Δ^{α}-butenolide (IV). This has recently been prepared by Elvidge, Linstead, Orkin, Sims, Baer and Pattison[19]. Another related substance at the same level of oxidation and hydration is γ-carboxymethylene-butanolide (V)[20]. Incubation experiments were accordingly carried out with these unsaturated lactones, β-ketoadipic acid being tested for by colour reaction and, in some cases, by isolation from the reaction mixtures.

The Δ^{α}-unsaturated lactone (IV) gave strong positive results, the isomeride (V) being negative. Table 2 summarizes these experiments, positive signs denoting the extent of appearance of β-ketoadipic acid. Control experiments on the substrate together with a boiled enzyme solution gave entirely negative results under the same conditions.

In summary, γ-carboxymethyl-Δ^{α}-butenolide (IV) is converted to β-ketoadipic acid, appreciably faster than is *cis-cis*-muconic acid, which is, in turn, faster than catechol. We therefore propose the reaction mechanism given in Table 3 for the missing stages in the total process.

The essential stages are (*a*) addition of water or isomerization; (*b*) migration of the double bond; (*c*) ketonization of the enol corresponding to the βγ-unsaturated lactone (VI). We do not know whether the tautomeric change (*b*) occurs between the open-chain hydroxy acids or their lactonic counterparts. The lactone (VI) is as yet unknown, but the overall changes (I) → (IV) and (IV) → (II) have been realized in purely chemical reactions (see ref. 19; also Kuehl, Linstead and Orkin[21]), making it highly probable that the scheme is essentially correct.

It is particularly interesting that the γδ-unsaturated lactone (V) is not an intermediate in the biochemical transformation (I) → (II), although both of the steps (I) → (V)[19] and (V) → (II)[20] have been effected *in vitro*.

There is a significant difference between the microbiological reactions and the corresponding metabolic processes in mammals. It has long been known that the feeding of benzene leads to the excretion of muconic acid in the *trans-trans* form. This has recently been carefully confirmed by Parke and Williams[22]. Some process of stereochemical inversion must intervene in the mammalian metabolic processes.

One of us (W. Charles Evans) is grateful to the Royal Society for a grant.

INSTRUCTIONAL FILM RESEARCH IN PENNSYLVANIA

The Pennsylvania State College Instructional Film Research Program, which is still in progress, exceeds in scope any previous research on the instructional film. It was begun in 1947, under the sponsorship of the Special Devices Center of the Office of U.S.A. Naval Research, and is now controlled by a Joint Services Advisory Committee of both the Army and the Navy. These Departments are interested in securing improvements in the instructional film, because they use the film for training purposes. They are also anxious to discover how far the film may displace—rather than merely aid—a skilled instructor. But the research—in which a number of divisions of Pennsylvania State College are co-operating—is of a fundamental kind. The results being obtained are of importance to all who use or make educational films.

An account of the work is given in a series of reports issued by the Special Devices Center, Port Washington, N.Y.; application for which can be made to the director of research, Dr. C. R. Carpenter, Pennsylvania State College, U.S.A. (In preparing the present article the reports chiefly consulted were four Technical Reports S.D.C. 269-7-6, 9, 10, 13; two Progress Reports 11-12, 14-15-16; Incidental Report No. 1; and Special Report No. 2.)

A general method of experimentation has been to produce different versions of a film, and to show them to matched samples of an appropriate audience. Tests, either of the objective multiple-choice question type or of actual performance, are then used to determine the relative teaching effectiveness of the versions. The films used in the experiments have been sound films, predominantly of the commentary-picture type.

Some of the main conclusions so far reached may be characterized as confirming previous opinion. The need for limited and specific objectives in instructional films is much stressed. The rate of development (that is, of putting forward new facts and ideas) of most present-day instructional films is too fast. Good projection and related conditions are of prime importance.

Many of the conclusions are on matters of technique about which, without details of the Pennsylvania experimentation, it would be impossible to form an opinion. In teaching a manipulatory task, the view given should as nearly as possible correspond with that of the learner in performing the task. There is an optimal level for the amount of verbal explanation (found to be about a hundred words a minute for the films used). To establish learning points, commentary should usually be in advance of the picture. The imperative form of address appears the most effective, and the third person passive least effective. There is no advantage in colour, except where it supplies determining learning cues, nor in background music for films of the commentary-picture type. Educational film sessions can last up to one hour with no decrease in effectiveness of teaching. The prestige attached by an audience to the principal exponent in a film increases the influence of the film on attitudes and factual learning from the film. Visual or sound attention-gaining devices, which are themselves irrelevant to the subject-matter, are no advantage.

The most provocative conclusion derived from the experiments is perhaps the one which states that a body of factual information can be taught as well by films alone as by standard lecture – text-book methods. This would seem to imply that films in some circumstances may displace the teacher in the classroom or lecture theatre in a more far-reaching sense than has formerly been realized, and for longer periods. But the Pennsylvania conclusions also make clear that an indispensable part is played by the teacher in 'face-to-face leadership'.

C. Denis Pegge

FILARIASIS IN THE PACIFIC

WHAT should be regarded as an important step forward in the welfare of the Pacific region and the very varied races that populate its myriad islands has been the creation of a South Pacific Commission with representatives from the widely scattered peoples of this area. The first conference of this newly constituted international body met in Suva during April and May 1950, under the presidency of the Governor of Fiji, Sir Brian Freeston. On the recommendation of this conference a congress in Tahiti of experts on filariasis and elephantiasis was arranged, and met during August 21–September 1, 1951, under the presidency of the Governor of French Oceania in the meeting room of the Representative Assembly at Papeete. Dr. E. Massal, a member of the South Pacific Commission, was elected chairman.

The proceedings of the congress have appeared, with commendable promptitude, in some twenty-two typewritten double-sided sheets. If the nature of the headings and the abstracts of the proceedings are any measure of the labours of this congress, then certainly it must be confessed that an immense amount of work was accomplished. It is gratifying to note that, taking part in the congress and thus adding to its international character, were representatives from Oceania as well as from France, the United States, New Zealand and Australia.

The work of the congress was divided under a number of headings. Under parasitology it was agreed to consider the local filaria as the Pacific variety of *Wuchereria bancrofti*, as suggested originally by the reviewer, and it was regarded as essential that the minute morphology of the adult stages should be worked out, that studies should be undertaken on the longevity of this parasite and its intermediate immature stages in the human body, and that a review of periodicity throughout the Pacific should be made. Under entomology, a paper on the mosquito vectors of human filariasis in Oceania was read by Dr. L. Rosen, of the School of Medicine, University of California, paying special attention to the *scutellaris* group of *Aëdes* with particular reference to *A. horrescens*. A film on the filariasis control programme in Tahiti was shown. It was further urged that experimental studies on mosquitoes in each area should be made to determine their potentialities as vectors of *Wuchereria* with special reference to the ability of *W. bancrofti* to develop in *Culex fatigans* in Polynesia and Melanesia. Dr. E. R. R. Brygoo, director of the Institut Pasteur, Saigon, presented a paper on the epidemiology of filariasis in the South Pacific, in which the example of New California was adduced, where neither Anopheles nor the *scutellaris* group of *Aëdes* are found, but where filariasis is widespread. The possibility of *W. malayi* being present in New Guinea was raised. The value of intradermal diagnostic tests was discussed, and the result obtained in Tahiti, Fiji and New Caledonia was compared with indefinite results. A new flocculation test was demonstrated by Dr. W. H. Wright, chief of the Laboratory of Tropical Diseases, National Institutes of Health, Bethesda, United States.

Under the heading of clinical pathology, Dr. P. E. C. Manson-Bahr, physician-specialist, Fiji, read a paper in which he proposed a conception of the infection occurring in three manifestations—primary or allergic, secondary or carrier state, and tertiary or obstructive; and it was agreed that this should form a working basis and that further investigations into the exact mechanism of elephantiasis should be carried out. Under treatment, Dr. W. H. Wright stressed the inadequacy of information of the lethal action of 'Hetrazan' on the adult worms. The role of anti-histamine drugs and antibiotics, such as penicillin, was discussed. The control and prophylaxis of bancroftian filariasis in the South Pacific was in the hands of Dr. H. K. Beye, field director of the Pacific Tropical Diseases Foundation, University of California, who cited instances where mosquito control had resulted in decrease in the microfilaria rates. Present observations relating to mass drug therapy and mosquito infection rates indicated that the most effective procedure is to keep the blood permanently free of microfilariæ. Dosage schedules of 'Hetrazan' now under investigation give promise of meeting this object. The value of educational and other measures was discussed. Especial importance was paid to the training of native personnel in filariasis control. The subjects of standardization and procedures regarding blood examination and documentation had universal support. Standard methods of recording mosquitoes or their larvæ, the laboratory diagnosis for microfilariæ, the recording of clinical manifestations and standards for intradermal tests were agreed upon.

An annotated bibliography of filariasis is being drawn up especially as regards the South Pacific. Finally, it was decided to publish the final report of the conference as a public document.

As the original work on filariasis in the Pacific was undertaken by a member of the staff of the London School of Tropical Medicine in 1910, and as his results were reinforced and expanded later by O'Connor, Prof. P. A. Buxton and others, it is a considerable source of satisfaction to record that, not only has their work been confirmed, but also that it is now being placed upon a practical basis, so that this, the chief scourge of the Pacific, may soon be eliminated altogether. PHILIP MANSON-BAHR

THE ANCIENT KHMER EMPIRE

AN entertaining and scholarly history of the Khmer Empire from the first to the fifteenth centuries, entitled "The Ancient Khmer Empire"*, has been written by L. P. Briggs. The data are derived from Chinese dynastic histories and Oriental travellers' accounts; Sanskrit and Khmer epigraphy; Buddhic and Brahmanic iconography; architecture, art and sculpture; bas-reliefs; and excavations.

Three periods are distinguished: the Funan (first to sixth centuries); the Chenla (sixth century to 802); and the Kambuja or Angkor (802–1431). The Funan period is that of a small kingdom on the Mekong delta, inhabited by a people who may have had negrito racial elements and have spoken a pre-Khmer Austro-Asiatic language. They are believed to have been conquered in the first century by a foreign invader (possibly Malay) who married their queen and introduced clothing among their women. Direct relations with India and China date from the third century. An Indian Brahman is recorded to have become king of Funan in the fifth century, and to have introduced, among other customs, state worship of the Siva-linga and a Central Indian alphabet.

Funan was conquered and became a vassal kingdom of Chenla to the north in 550, the Chenlas being a Mon-Khmer people who had obtained their own kingdom by an earlier conquest of the Chams. The Chenla people were already acquainted with the Siva cult and with the Sanskrit Puranas and Epics. The united kingdom of Chenla and Funan was temporarily conquered by the Malays some time in the eighth century.

The Kambuja period opens with a line of kings who considered themselves incarnations of Siva and who founded a Devaraja cult, each new king being appointed by the head of a family of Brahman *purohitas*, among whom, unlike the rest of the population, descent was matrilineal. This was the classical period of Cambodian history, marked by a great expansion of the empire, a magnificent flowering of architecture and art, and a unique syncretism of Saivism, Vishnuism and Mahayana Buddhism. With the increasing influence of Buddhism, the Devaraja cult gave place to the cult of a Buddharaja. There was a decline in art and architecture in the thirteenth century, probably coincident with the introduction of Hinayana Buddhism. The period ends with the Siamese sacking of Angkor in 1431, and the removal of the capital to the south-east part of the kingdom. Though the Khmers gave to the world no system of administration or ethics, no literature and no philosophy, their civilization saw the summit of Oriental architecture and decoration.

KATHLEEN GOUGH

FOREST RESEARCH IN SWEDEN

VOL. 39 of the memoirs of the Forest Research Institute of Sweden* contains a number of articles of varied interest. Erik Holmsgard discusses height increment, development of the crown, self-pruning, etc., in young beech stands. His investigations seem to show great variations in height increment in various years, and this does not necessarily depend upon changes in climate; thus, the highest trees in a young stand will not necessarily remain so. The growth in height of the lateral branches and the height increment of the lower trees are more influenced by the light conditions than by the climate. It is impossible to give here the author's detailed conclusions, for which the paper should be consulted.

Henrik Petterson deals with the application of the new forestry conservation law passed in 1948, which aims in general at economic forest utilization with a constant yield. Mr. Petterson admits that it may seem futile under present conditions, when the outlook is so uncertain, to attempt to direct the utilization of forests toward an economic goal. The law differentiates between well-grown forests and those which are badly grown or tended: the former, apart from thinnings, may not be clear-felled without the consent of the Forest Conservation Bureau; and the latter must not be treated in such a manner as to result in further deterioration. Further, such measures must be carried out as will result in an improvement of the stocking of the forest within a reasonable time. The paper discusses the methods by which the law can be carried out. There is no indication that it proposes anything quite so drastic as the dedication scheme envisaged by the Forestry Commission in Great Britain.

A third paper of interest, by Marianne Lekander, treats of the invasions of insect pests in the Swedish forests during 1741–1945. The author has studied the whole of the literature—the forestry and entomological, administration and departmental reports of the State and reports of forestry conservators and the institute of research—and the paper appears to be an admirable piece of work. Mass invasions or slighter ones occurring more often are classified for each species of insect in a chronological order and are given for each of the forest conservancies in each province. A tabular statement is given at the end of the paper enumerating the chief pests of the forests during a period of fifty years, 1896–1945. An alphabetical list of the insects mentioned is given in Latin and Swedish.

Another paper, by Lars Tiren, is "On Clearing Spruce and its Significance for the Reforestation of Spruce Forest Clearings in Northern Sweden". The main objective was to study the nature and abundance of the seed and resulting seedling growth occurring from the spruce trees left standing in the forests in northern Sweden, and a good opportunity occurred in the good spruce seeding year 1942–43. In these northern spruce forests the future crop largely depends upon the poor type of tree called 'clearing spruce' or 'remnant spruce'. Even though these trees often appear very insignificant and inefficient for the purpose required, they do in effect function as seed-bearers, though often assisted by contributions from any forest border trees surrounding them. Briefly, the study has shown that some artificial help can assist, which may consist of raking under the trees or burning under them, providing a sufficiency of good trees remains to assist the others. Much further research requires to be carried out, which should prove of value to other parts of the world where forests growing under the same type of conditions exist.

CHEMICALS IN FOOD

THE United States Congress established in June 1950 a Select Committee, known as the Delaney Committee, which was given the task of assessing the dangers to public health arising from the increasing use of chemical substances in food manufacture and from the presence in foods of residues from the pesticides now widely employed in agriculture. This Committee has issued its preliminary findings* together with a full report† which is an important document embodying in its eight hundred pages the views of some seventy scientific workers, physicians and industrialists who appeared as witnesses.

The Committee heard the striking evidence submitted by the officers of the Food and Drug Administration, who stated that 704 extraneous substances were thought to be in use; of these, only 428 were considered harmless as normally employed, leaving a further 276 of which the safety was open to question. Attention was directed to a conflict of opinions regarding the suitability of various compounds. There are several which were at one time considered harmless and which found a place among food ingredients; later investigations established their toxic character. In this category are p-phenetyl urea, used for more than fifty years as a sugar substitute; chloracetic acid, a preservative for wines; and thiourea, an anti-browning agent for fruits. The dyestuff butter yellow served for many years as a food colour before its carcinogenic action was recognized, and lithium chloride was considered safe until it was shown to be fatal to persons living on a low salt (sodium chloride) diet.

The above substances are no longer employed, but there are others in use which are the subject of controversy; and although those materials which act as preservatives, anti-oxidants and mould inhibitors are added to food in very small quantities, others such as the synthetic emulsifiers used in the United States baking industry may be present in considerable amounts. Many witnesses pointed to the dangers that could result from the incorporation of these newer ingredients in a staple commodity such as bread.

Consideration was given not only to those substances which are added deliberately to foods to produce some desired effect, but also to others which may become associated with foodstuffs by accident. Among these are the surface-active agents employed in the cleaning of food utensils and machinery, and the pesticides, such as DDT, which may adhere to crops and find their way into foodstuffs. The very properties which make these substances so effective in the control of lower forms of life may lead to their absorption by plant tissues and to their injurious effects on higher animals.

Testimony was given regarding the difficulties experienced in devising suitable methods for the accurate estimation of many of the newer synthetic substances, especially at the low levels at which they are likely to occur in foods. Sound practical analytical methods are essential if there is to be adequate control of the degree of contamination of foods and if the pharmacological properties of the compounds are to be investigated.

Many scientific workers stressed the necessity of carefully designed toxicity studies. They pointed out that, in the past, the main emphasis had perhaps been on acute toxicity tests to discover the levels at which a substance would produce deaths in experimental animals within a short period of time after it had been given by mouth or by injection. In the light of experience gained over the past decade more detailed investigations are required—feeding experiments at different levels on several species of animals over a period of perhaps two years, together with a thorough study of the metabolism of the substance under discussion, its effects on the tissues of the experimental animals and its relation to growth, reproduction and lactation. The results of some of these *chronic toxicity* studies were quoted; there were substances which appeared to be harmless in short-term experiments—in that they did not cause death immediately following ingestion—yet small amounts accumulated in the body and ultimately produced permanent injury.

Experiments on the chlorinated hydrocarbon DDT were described which demonstrated that DDT appeared in the flesh of chickens, cows and sheep which had eaten crops sprayed with the pesticide. It was present also in eggs and in milk. Moreover, lactating cows in a byre treated with DDT secreted in the milk within forty-eight hours quantities of 2 parts per million. This amount was shown to be significant in that DDT when fed to laboratory animals was stored in the body fats; diets containing as little as 5 parts per million produced liver injury in rats. Other pesticides are even more highly toxic, and it was suggested that some should be banned completely from use on food crops.

---

* Investigation of the Use of Chemicals in Food Products. 1951. Union Calendar No. 1139. Report No. 3254. (U.S. Gov. Printer, Washington, D.C.)

† Chemicals in Food Products. Hearings before the House Select Committee. 1951. (U.S. Gov. Printer, Washington, D.C.)

Many other topics were reviewed by the Delaney Committee; for example, the impairment of the nutritive value of prepared foodstuffs through the replacement of naturally occurring constituents such as fat by synthetic materials which cannot be utilized by the body and which may interfere with the normal absorption and metabolism of nutrients. Information was also given regarding the unforeseen consequences of the introduction of synthetic hormones into poultry husbandry; mink fed on the offal of chickens treated with hormones became sterile, an observation which has naturally led to a demand for a full inquiry.

There is now a substantial body of public opinion in the United States which favours legislation to deal with the various problems outlined above, and this proposal is supported by members of the medical profession and by others working in the fields of biochemistry and nutrition. The central issue under discussion is how to frame suitable legislation which, on one hand, will provide adequate protection for the consumer and, on the other, will also give freedom for new and legitimate developments in agriculture and food technology.

FRANCIS AYLWARD

MECHANICAL ENGINEERING RESEARCH ORGANIZATION

REPORT FOR 1947-50

UNTIL recently it was clear that in Great Britain research in mechanical engineering suffered from lack of any central co-ordination: a considerable amount of work was being done in government, industrial and university research laboratories, but in some branches the researches carried out were insufficiently fundamental, being directed towards the solution of immediate problems. A new organization was clearly needed, both to conduct basic research not carried out elsewhere and to serve as a focal point for all other research work. To meet this need the Mechanical Engineering Research Board was appointed in 1946 to advise on the organization and equipment of the government-sponsored Mechanical Engineering Research Organization, to which funds amounting to some £300,000 a year were allotted.

The first report of the director of the Organization has now been issued*. It is prefaced by a report of the Board, which reviews the broad issues involved and the progress achieved in the establishment of this new Organization. It gives a clear and concise account of the whole situation: the objectives, the resources available, the constructional work complete or projected, the research now in hand or planned, and the collaboration with other research bodies.

A new organization of this type cannot grow without any roots: it is necessary to train the teams who will work together, before they can be transplanted to other premises. There must be a proportion of well-established lines of research in addition to those that are quite new. In this case the greatest debt is to the Engineering and Metrology Divisions of the National Physical Laboratory, from which the nucleus of the Mechanical Engineering Research Organization has been formed.

It was decided, on broad national grounds, that the new laboratory should be situated in Scotland. The site adopted is at East Kilbride, near Glasgow, together with temporary premises a few miles away at Thorntonhall, and sufficient laboratories and essential services are now ready at East Kilbride for research work to begin there. The establishment is being organized into seven main divisions, the work of each being under the supervision of a committee of experts from industrial and other research laboratories. In addition, a considerable amount of extra-departmental research is being undertaken in collaboration with each division.

The first director of the Organization was Dr. G. A. Hankins, formerly superintendent of the Engineering Division of the National Physical Laboratory. Since his death in November 1950, Dr. D. G. Sopwith, his successor at the National Physical Laboratory, has been in charge on a part-time basis (see p. 769). His report gives a fairly complete picture of the work done during the first three years of the existence of the Organization. In the early stages the main emphasis was naturally on the formulation of future research programmes; this changed to the detailed design of laboratories and equipment and the recruiting and training of staff. The total staff in 1948 numbered only seventeen, but by December 1950 the scientific and technical staff had increased to sixty-three, together with a roughly equal number of ancillary laboratory, office and industrial staff.

The progress of the various researches and future work planned by each division is detailed, together with an account of extra-departmental projects. Even an outline of all the work undertaken or contemplated is impossible in this article. It ranges from the comparatively familiar tests and techniques used in the testing of materials to the development of the use and analysis of mechanisms, a branch of engineering science which has remained practically static for some fifty years. It is apparent how closely allied many of the researches are to other fields of scientific, as opposed to technological, research; it is, of course, quite impossible, and undesirable, to make any such distinction. It is intended, however, that the work of the Organization shall be carried through to the development stage, should it be considered essential to do this in order to make apparent the industrial advantages to be gained from the results of basic work.

This publication is likely to prove of interest to those engaged in scientific research of any sort, and it can be recommended as giving a clear idea of the progress and aims of the new venture. No longer can it be maintained with justice that technological research in Great Britain lags behind general scientific research, either in relation to its fundamental nature or to the breadth of outlook of those concerned with it.

Existence and Nature of the 'Positive Particles' near a Source of Radium E

We have recently taken two thousand pairs of photographs of the cloud-chamber tracks of particles emitted from radium E. The rays entered through a small aperture from a source situated outside the chamber, across the centre of which was stretched a foil of aluminium of mass 0·046 gm./cm.^{2}. The applied uniform magnetic field was about 220 gauss, and almost all the tracks showed a curvature indicating a negative charge. In a total of some 12,000 tracks, not more than twenty were found which proceeded from the source and which had a curvature in the opposite direction from that of the negative β-particles. Applying further very rigorous criteria of perfection, we can select three tracks *A*, *B* and *C*, of which *A* and *B* have $H\rho$ about 2,400, while the value for *C* is the highest recorded at 3,600.

It may easily be shown by the application of the conservation laws of energy and charge in the radium E→radium F transition that there is insufficient energy for positron–electron pair production with the observed momenta. Proceeding systematically to consider the values of e and m which would satisfy the observed values of $H\rho$, the available energy in the radioactive transformation and the conservation of charge, the remarkable fact emerges that the observations are plausibly satisfied only if $e = e_0/2$ and $m = m_0/2$ or zero, where e_0 and m_0 are the electronic charge and mass. The former particle would have e/m identical with that for an electron and would be indistinguishable from it in several qualitative aspects. Now particle *A* fails to appear on the other side of the foil, and in this respect it corresponds to the observed behaviour of many of the negative β-particles of similar $H\rho$. On the other hand, particle *B* appears to traverse the foil with little loss in energy, which is what might be expected for a particle with the high kinetic energy to be associated with a particle of zero rest mass. These ideas have been applied to the examination of earlier results obtained by other workers in this field and consistent results are obtained.

However, apart from their feeble intensity, it still remains very difficult to explain why such particles have not been detected by a conventional 180° β-ray spectrometer, since the action of the latter depends only on the values of $H\rho$ as a measure of the momenta of the particles, and is independent of the particular values of e/m. Further consideration of our photographs shows that, while the probabilities are remote, it is still possible to explain the 'positive tracks' without the introduction of any particles other than the negative β-particles. Particle *A* could be due to a scattered negative β-particle which has been deflected through about 140° just before reaching the foil, for in earlier work on large-angle scattering of fast β-particles by nitrogen nuclei, one such deflexion occurred in a similar total length of track. It must be pointed out, however, that to satisfy the experimental observations, not only is a scattering angle of this magnitude required but, in addition, the scattered particle must proceed directly towards the source in the plane of the chamber throughout its entire length. There is also the grave difficulty that the track, which might correspond to the parent before scattering, is seen to be in a different plane from the scattered track.

Since the source was situated outside the chamber, the chances of radioactive contamination were reduced to a minimum, although it was not completely absent. With regard to particle *B*, the two portions of the track which appear on each side of the foil could arise from independent events where one track originates from contamination on the chamber wall and proceeds to the foil, while the other could come from contamination on the foil itself (at the identical spot and at the same time as the first track) and then proceed to the source. The two tracks would have to be of about equal momenta and to proceed in the same direction at the foil. The chance of all these conditions being satisfied simultaneously appears utterly remote, even bearing in mind the fact that the momentum involved in these cases is, in fact, that corresponding to the most probable momentum of the negative β-particle spectrum. On the other hand, it can be shown on plausible grounds, based on the fact that the most probable β-particle energy is about one-third that of the upper limit of the β-particle energy spectrum, that this $H\rho$ is also the most probable value likely to occur if the existence of the new particles were real.

In view of the work already done, together with the present results, it seems unlikely that more cloud chamber experiments of this type will throw further light on this extraordinarily elusive problem; but it would be interesting to use other techniques for detecting the existence of these 'positive particles' now that the present work has suggested possible values of mass and charge. There does not seem less evidence for the reality of their existence than exists for the neutrino at present.

An Experiment on Nuclear Alignment: the Anisotropy of γ-Radiation from Oriented Cobalt-60 Nuclei

Radiations from radioactive nuclei oriented at random are isotropic; but if the nuclei are even partially aligned, an anisotropic distribution should in general be found provided I is greater than $\frac{1}{2}$, as shown by Spiers[1]. In order to align nuclei, one makes use of the energy differences between the various orientations of the nuclear spin. By cooling to low enough temperatures, the lower levels will be preferentially populated, and in suitable systems this corresponds to a spatial alignment. In general, these energy differences are so small that temperatures obtainable only by adiabatic demagnetization must be used.

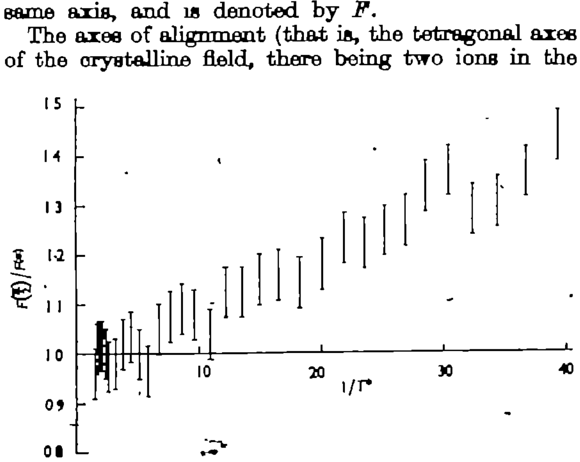
Besides the obvious and quite general method for producing these energy differences by an external magnetic field[2], the following more specific mechanisms have been suggested: by interaction between the nuclear electric quadrupole moment and the crystalline field (Pound's method[3]), or by the magnetic interaction between the nuclear spin and the resultant magnetic moment of the electrons in a paramagnetic ion. In this latter case the electronic moments must first be aligned, and this may be done either by a small external magnetic field (Gorter–Rose method[4,5]), or through the interaction of the electrons with the crystalline field (Bleaney's method[6,7]). Gorter, de Klerk, Poppema, Steenland and de Vries[8] carried out preliminary experiments using the Gorter–Rose method on the γ-emission from iron-59, and on neutron absorption in gadolinium, but inconclusive results were obtained. Thus, in the case of iron-59, only one experiment is reported to have given an anisotropy, which, however, was only 2 per cent with an experimental error of 1 per cent.

In the experiments which we report here Bleaney's method was used. The substance was a mixed Tutton salt with the composition (1% Co, 12% Cu, 87% Zn) $SO_4.Rb_2SO_4.6H_2O$. Copper acted as cooling agent, zinc as a non-magnetic diluent to reduce magnetic interaction and rubidium was chosen as monovalent cation so as to reduce exchange interaction[9]. This enabled us to attain a lower temperature than would have been possible with a concentrated salt, namely, about 0·02° K. from an initial H/T of 30,000 Oe./°.

Six single crystals of a total weight of 4 gm. containing about 70 microcuries of cobalt-60 were mounted in a demagnetization cryostat with parallel crystallographic orientation, and the K_1 and K_2 axes (two of the principal axes of susceptibility) in a horizontal plane. The γ-radiation was detected by four Geiger counters (G.E.C. Type *GM*4), two each along the K_1 and K_2 axes of the cobalt ions, placed at 10·5 cm. from the centre of the specimen and subtending an angle of 13°.

The counting-rate was taken for successive 10-sec. periods while the specimen warmed up, and, at the same time, readings were taken of the magnetic susceptibility of the specimen. It was necessary to use short measuring times because the specimen remained at a low enough temperature for about five minutes only. This was on account of the very small thermal capacity of the salt, and of the heating-rate of some 150 ergs/min., composed of the self-heating due to the radioactivity of the crystals, and of a small heat leakage. Frequent tests showed that the counters were stable, and that the counting-rates followed the normal statistical distribution; this has been assumed in evaluating the probable error of individual measurements. The number of counts observed in a particular 10-sec. period was normalized to the mean counting-rate obtained in the same counter when the specimen had warmed up to 1° K. This figure for each particular counting period was averaged with respect to the two counters on the same axis, and is denoted by F.

The axes of alignment (that is, the tetragonal axes of the crystalline field, there being two ions in the unit cell and hence two alignment axes) are perpendicular to the K_2 axis, and each makes an angle α (= 37·5° in cobalt rubidium sulphate[10]) with the K_1 axis, that is, with the horizontal plane[7]. Accordingly, the two values of F are denoted by $F\left(\frac{\pi}{2}\right)$ and $F(\alpha)$ respectively. Altogether, thirteen demagnetizations have been carried out on four different days under different experimental conditions, and all gave consistent results. Anisotropies of up to 44 per cent were observed, and the result obtained from one demagnetization which gave the maximum effect is shown in the accompanying graph, where $F\left(\frac{\pi}{2}\right)\Big/F(\alpha)$ is plotted against $1/T^*$. The 'magnetic temperature' T^* (defined by means of Curie's law) is not very different from the absolute temperature for this substance.



Variation with temperature of the anisotropy of γ-ray emission from cobalt-60 in dilute cobalt rubidium sulphate

In order to eliminate any effect due to individual counters, the experiments were repeated with the pairs of counters interchanged. It was also shown that the observed effect was not due to extraneous magnetic interference, because, on carrying out several demagnetizations starting from higher temperatures which resulted in little or no cooling, no anisotropy was observed.

The maximum effect observed by us, namely, 1·44 ± 0·05, is, judging from the shape of the curves and knowledge of the entropies, unlikely to be the saturation value. In comparing our values with theory it must be borne in mind that Spiers's discussion relates to γ-emission from aligned nuclei. In our experiment it is the cobalt-60 nucleus which is aligned, whereas the γ-radiation is emitted by the daughter nucleus nickel-60 formed by β-decay. If this β-transition from cobalt-60 to nickel-60 is accompanied by a change of angular momentum, the alignment may be partially destroyed. This has been discussed by Steenberg[11], who showed that no great reduction in the anisotropy of the γ-rays was to be expected for the possible angular momentum changes involved in the cobalt-60 β-decay. The maximum value of our effect is consistent with the saturation value predicted by Steenberg (1·6–1·7, according to the nature of the β-transition).

This experiment would not have been possible without the guidance and co-operation of Dr. N. Kurti and Dr. H. Halban. We wish to thank also Dr. B. Bleaney for stimulating discussion, and Prof. F. E. Simon for his continued advice and encouragement. Acknowledgment is due to the Department of Scientific and Industrial Research for generous help which made this research possible.

Detection of Circularly Polarized γ-Rays and the Production of Polarized Electrons

In a recent communication[1], it was pointed out that the $(n-\gamma)$ processes induced by polarized neutrons will in general lead to partially or totally polarized end-products. In particular, it was shown that for spin values of the initial and resulting nucleus of 0 and $\frac{1}{2}$, respectively, the γ-ray emitted in the direction of the spin of the incident neutron is completely circularly polarized. The same result holds true for the pair of spin values $\frac{1}{2}$, 0.

I wish to report now on some simple results concerning possible experiments with circularly polarized γ-rays. Choosing a special case of the Compton effect in which the quantum is scattered backwards and the electron forward in the direction of incidence, one finds that for moderately large quanta $\left(\frac{h\nu}{mc^2} \gtrsim 3\right)$ and an unpolarized electron initially at rest, the scattered electron is almost totally polarized, its spin pointing in the direction of propagation.

Similarly, if the electron is initially suitably polarized, the scattering cross-section will vary (in the approximation used) between zero and twice the value obtained for an unpolarized electron.

A detailed discussion, including that of other interactions between γ-rays and electrons, will be published in the *Physical Review*.

The Helix as a Linear Accelerator for Protons

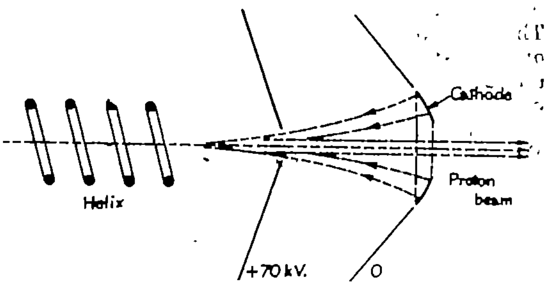
An electrostatic generator, designed for 4 MV., has been built at this Laboratory to accelerate positive ions, and the possibility of increasing the energy of protons from this machine to about 20 MeV. by means of a linear accelerator has been considered.

The disk-loaded wave-guide type of linear accelerator used for electron acceleration is impracticable for protons in this energy-range on account of the low phase-velocities required (0·1–0·2c). The high-frequency losses would be prohibitive and the tolerances in dimensions impossible to meet.

A more practicable form of proton accelerator is that suggested by W. Walkinshaw[1], consisting of a circular wave-guide made up of a closely wound helical wire. Roughly, the travelling wave tends to follow the wire and is slowed down in the ratio of the pitch to the circumference of the helix. More accurately, the phase-velocity can be calculated from an approximate field solution given by Pierce and Schelkunoff[2].

In a proposed design, assuming the helix radius to be 1 cm., the optimum free-space wave-length is found to be 1 metre. If the radio-frequency power flowing down the guide is 2 MW., an accelerator 11 metres long will accelerate the protons from 4 to 20 MeV. The power dissipated in the helix is 380 kW.; the remainder can be fed back from output to input through an external line and suitable phase-correcting network.

The chief difficulty in principle arises from the defocusing effect of the wave on the proton beam. Those protons which get caught up by the wave and accelerated with it oscillate slowly about a stable phase-point which lies in front of the peak of the axial field; that is, in the region where there is a radial component of electric field outward. This radial component would cause a proton beam of initial radius 1 mm. to spread and touch the helix in a distance of about 1 metre.



Possible arrangement of electronic gun

It is suggested that this may be prevented by sending a beam of electrons along the axis of the guide, in the opposite direction to the protons for convenience. The beam would be launched by some form of annular gun through which the proton beam could pass. The space charge per unit length of the electron beam must be sufficient to create a radial electrostatic field inward, equal to the maximum outward field arising from the wave. The energy of the beam must be such that no electrons are turned back by the wave at any point along the guide or at any phase of entry. Simple calculations indicate that a beam of 1 amp. at about 70 kV. is required. The electron gun may be pulsed in synchronism with the radio-frequency oscillator in order to ease problems of heat dissipation and X-ray intensity. An electron gun has not yet been designed, but the accompanying diagram suggests a general arrangement of electrodes at the output end of the helix.

It is further suggested that the spreading of the electron beam under its own space-charge forces may be prevented by applying an axial magnetic field along the guide by means of a long solenoid. The electrons then acquire a cycloidal component of motion in a plane normal to the axis, similar to the motion in a cylindrical magnetron. Assuming the initial radius of the beam to equal that of the proton beam (1 mm.), and using the magnetron cut off equation, one can calculate the magnetic field required to prevent the beam radius from exceeding the value needed to keep the proton beam properly focused. Values obtained in this way range from 870 gauss at the input end of the accelerator to 570 gauss at the output end. The divergent field at the open end of the solenoid may be used, with careful design, to guide the electrons from the annular cathode in towards the axis.

The spread of energy in the emerging proton beam will depend on how far the stable phase-point is in advance of the peak of the field. Taking this phase angle to be 35°, the maximum amplitude of phase excursion a particle can have is 70°. The maximum kinetic energy such a particle can have relative to the wave is that due to this phase excursion through the axial field, and amounts to 50 keV. at the output end. Converting this to velocity, transforming to the laboratory frame of reference, and reconverting to energy, one finds that the energy spectrum of the output beam has a maximum value of ± 10 per cent, or approximately ± 7 per cent at half amplitude. This spread can be reduced by reducing the angle of the stable phase-point, with a corresponding reduction in number of protons caught up per cycle by the wave, and hence in the mean output current.

We wish to thank Messrs. R. L. Fortescue, W. W. Walkinshaw and J. S. Bell[3] for valuable discussions and suggestions in connexion with this work, and we are indebted to Dr. T. E. Allibone for permission to publish this communication.

Polymorphism arising from Screw Dislocation

Frank[1] predicted from theoretical considerations that crystal growth may proceed owing to the presence of screw dislocations. Spiral growth-steps confirming these ideas were observed by Griffin[2] in beryl crystals and by Dawson and Vand[3] in *n*-paraffin crystals. The dislocation responsible for the growth of a crystal may be described by means of a Burgers vector. For a simple screw dislocation, this vector is one structural unit in length and perpendicular to the growing face, so that a spiral growth-step one unit in height is generated. In a certain number of cases the Burgers vector is several units in length, the original length being determined by the detailed shape of the primary nucleus or other accidents of growth.

In many layer structures, several kinds of stacking having nearly equal energies are possible, the best-known example being the cubic and hexagonal stacking of layers of spheres. If the crystal grows by successive deposition of fresh layers, then a random disorder in the succession of the layers would result. However, if the crystal grows by means of a screw dislocation, then it consists of a single sheet spirally wound around the screw dislocation, the pitch of the screw so formed being equal to the Burgers vector. When the growth-sheet is several packing layers thick, any original packing mistakes in the sheet would repeat themselves throughout the crystal with the periodicity of the Burgers vector. Crystals so formed may be regarded as exhibiting polymorphism, the particular polymorphic form being defined by its unit-cell dimension and the arrangement of the stacking within the unit cell.

In order that this type of polymorphism could be observable, the following conditions must be fulfilled: (*a*) more than one possibility of stacking of layers should be available; (*b*) the crystal growth should proceed by means of screw dislocations having a Burgers vector more than one structural unit in length; (*c*) the screw dislocation system should be stable, that is, the Burgers vector should remain the same throughout the growth of the crystal.

If the last condition is not fulfilled, then twins or multiple intergrowths, each in a different polymorphic form, would result.

It is possible that this type of polymorphism may be quite widespread in Nature. The best example is that of silicon carbide, which is known to exhibit a wide variety of polymorphic forms. In silicon carbide, the screw dislocations must be very stable, as large crystals all in the same polymorphic form occur. Another substance which shows this type of polymorphism is graphite; but, owing to its softness, its polymorphism can be studied only on very small crystals. A more detailed discussion will be published elsewhere. I wish to thank Prof. J. Monteath Robertson for his interest, and Drs. I. M. Dawson and F. C. Frank for valuable discussion.

Note added in proof. In a recent paper, Frank[4] has advanced a similar explanation of polymorphism (polytypism) of silicon carbide.

Growth Spiral Patterns on Carborundum Crystals

Observations on growth spirals on carborundum crystals have been reported earlier[1], affording experimental evidence of Frank's theory of crystal growth depending upon dislocations. Some new and unpredicted features of these growth spirals are reported here.

In Fig. 1 is shown part of an interlaced spiral in which in any one orientation *seven* steps are seen to group together. On following these steps to the other side of the interlaced portion, the same sequence of spacing repeating itself has been observed (not shown in Fig. 1). Under low magnification these grouped steps give an appearance resembling optical band spectra.

On another crystal a similar grouping of *five* steps has been observed. In addition, on one face of a crystal the number of steps grouped together has been observed to change in certain regions.

These features can be explained thus. The different polytypes of carborundum have the Ramsdell's zig-zag sequence[2] or Zhdanov[3] symbol of $[(33)_n32]$. Using Frank's notation[4], the structure can be written as $[(\nabla\nabla\nabla\Delta\Delta\Delta)_n\nabla\nabla\nabla\Delta\Delta]$. Whichever layer has the slowest velocity of growth in any one orientation—say, the first ∇ after a series of Δ's—then it will repeat itself after six such layers, making the growth steps 15 A. high, until we reach the last layer $\nabla\nabla\nabla\Delta\Delta$, which will be only 12·5 A. high. After this the whole sequence will go on repeating itself. Thus, depending upon the number *n*, we will have a certain number of steps grouping themselves together. The observation of the changing number of grouped steps together suggests a change in type from one part of the crystal to another. This may account for the disagreement between crystal symmetry and X-ray diffraction data sometimes observed[5].

The observation of this grouping of steps is another visual confirmation by crystal growth patterns of the repeat sequence predicted by X-ray phenomena.

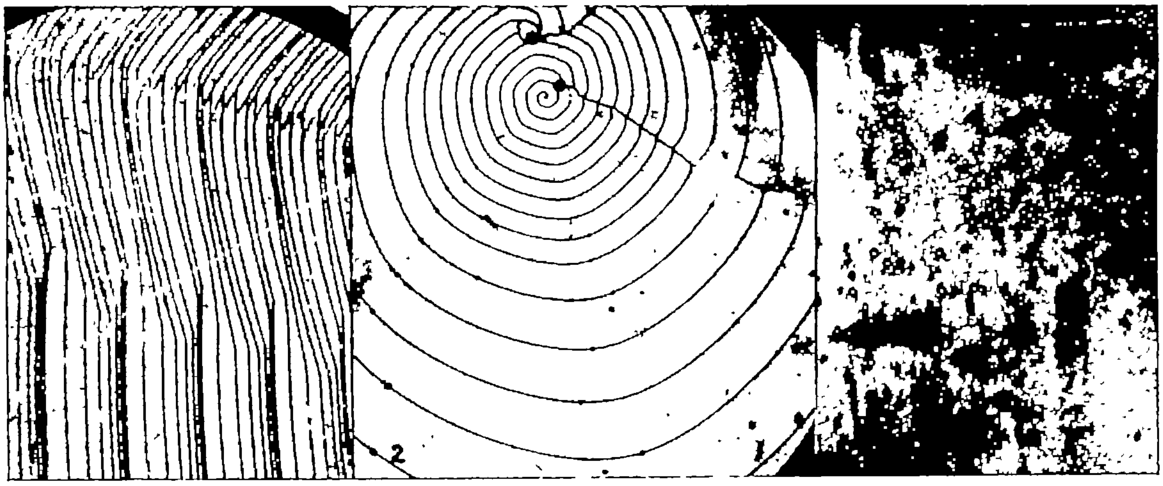

Fig. 2 shows a spiral in which spots are seen just on the edges of the steps. Their size generally increases as we go away from the centre.

Fig. 3 shows a number of hexagonal spirals originating from screw dislocations, the point of emergence of which is marked by a somewhat hexagonal spot. A large number of similar spots with no spirals attached to them are also seen. These are sometimes linearly arranged. At the Bristol Summer School (1951), where some of these pictures were presented, it was suggested by Dr. F. C. Frank that these may be the ends of edge dislocations.

I wish to express my thanks to Prof. S. Tolansky for his interest, and to the British Council for the award of a scholarship.

Relationship Between the Extinction Coefficient and the Particle Size

THE experimental determination of the relationship between the extinction coefficient and the particle size for spherical bodies having diameters less than about 50 microns is of considerable theoretical interest in the verification of certain aspects of the vector theory applicable to the problem, and also of practical importance in the application of the photo-extinction method of powder-size analysis.

For these reasons the relationship has received considerable theoretical and experimental investigation; but, even so, a study of the literature shows that the available data are conflicting.

Further examination of the problem, however, shows that the deviations occurring between the results of the different experimental determinations are probably due to errors arising from the following causes: (1) the suspensions tested are usually composed of ground mineral powders, and so the particles are, in general, not truly spherical; (2) the samples tested are usually sized for diameter by levigation and, owing to the limitations of the method, the size limits are often indefinite; (3) complete elimination of fine material from the sample is difficult, and even traces of residue introduce considerable error; (4) the calculated size characteristics of samples of particles, of size less than say 5 μ, are often unreliable due to errors introduced by Brownian movement and thermal currents in the fluid in which the samples are separated; (5) aggregation of the particles in the suspension occurring during the normal photo-extinction test is undetected, and it is probable that errors of unknown magnitude, arising from this cause, are frequently included.

In the present investigation these sources of error are either eliminated or the magnitude of their effect determined and an appropriate correction applied to the results.

For particles of size up to about 25 μ diameter, spheres of fused powdered glass and of polystyrene are used. The preparation of glass spheres of size greater than about this figure is not practicable so, in order to extend the size-range, a desert sand and a silica sand are used. The particles of these sands approximate closely to spherical, but a small correction for the deviation from sphericity is made upon the basis of the shape factors suggested by Heywood[1].

The glass and sand powders are sized within reasonably close nominal limits of size by repeated levigation, these fractions then being submitted to sedimentation in a photo-extinction apparatus which has been described elsewhere[2], and a curve of ln I_0/I plotted against the corresponding Stokes's diameter obtained—I_0 and I being the incident and emergent light intensities respectively.

From this curve is calculated the mean size and the size limits of the sample, and also the increment of ln I_0/I due to the material in this size-range. Furthermore, the approximate weight of the material, mainly of size less than about 2 μ, not removed by levigation, is computed from the curve and an appropriate correction to the concentration of the suspension determined.

The substitution of these corrected values in the equation of light transmission through a suspension of particles,

$$\ln I_0/I = 1\cdot5 \frac{Cl}{\rho d} K_e$$

llows the calculation of the corresponding extinction oefficient, K_e.

The extinction coefficient for the plastic spheres is etermined without recourse to corrections, the iameter as obtained from an electron photomicrograph being used.

It seems probable that by these means the rrors enumerated above are almost completely liminated.

The relationship of extinction coefficient and particle size as obtained from the present experiments s shown by the relevant points on the appended graph, and it will be seen that, in the range where he results for the different materials overlap, the oints applicable to desert sand agree well with hose for the glass spheres, and those for silica and agree well with those for desert sand; thus onfirming the accuracy of the correction for nonphericity.

The full line on the graph is considered to be the best line through these points; this line being drawn, or materials less than 10 μ in diameter, to correspond with the theoretical curve suggested by Stratton and Houghton[3], since there is considerable evidence of the validity of the results of these workers for this range, and also the experimental points fall well upon uch a curve.

The broken curve shows a portion of the solution uggested by Stratton and Houghton, and for diameters greater than about 17 μ an extension to he solution of Stratton and Houghton suggested, on heoretical grounds, by Brillouin[4].

Within the range 1–2 μ, the experimental data are canty, but it is interesting to note that two points determined by Vouk[5] fall well upon the curve of Stratton. These points, which do not fall on the curve deduced by Vouk and which appear to have received no mention in his thesis, give further confirmation to the curve of Stratton and Houghton for this range.

From these results it appears that the theoretical xtension of the curve of Stratton and Houghton, deduced by Brillouin, is of the form obtained by experiment, and hence that Brillouin's interpretation of the terms in the vector equations is correct.

The agreement between the theoretical and the xperimental results also supports the view that the full curve of the graph may be used with confidence in the determination of the size characteristics of fine powders by the photo-extinction method; the procedure for the application of such a curve to this problem has been given in detail elsewhere[6].

Improving the Performance of a Littrow-type Infra-Red Spectrometer

IN a recent communication in *Nature*, A. Walsh[1] suggested a means of improving the performance of a commercial infra-red spectrometer by adding extra plane mirrors so that the radiation traverses the prism four times instead of twice, and then chopping the partly dispersed radiation so that only the wanted radiation is interrupted and consequently measured. The advantages claimed are that the instrument is in effect converted into a double-monochromator with improved resolution and complete freedom from stray light even at 15 μ.

It is the purpose of the present communication to point out that similar ideas have been suggested previously, and to describe an alternative and perhaps simpler way of applying them to existing spectrometers.

Some years ago, Dr. W. C. Price (then with Messrs. I.C.I., Ltd.) explored the possibility of increasing resolution by traversing the prism four times instead of twice, as indicated in Fig. 1. Resolution is certainly improved, but two difficulties arise: (1) normally the entrance slit is curved to give a straight spectral image on the exit slit, but two extra traversals of the prism will introduce further curvature so that either the exit slit must have curved jaws also or the entrance slit must be given still greater curvature (Walsh does not mention this point in his letter); (2) with so many traversals of the prism, stray light, already troublesome in Littrow-type instruments, is likely to be further increased.

A natural development from Dr. Price's suggestion is to use a small plane mirror close to the entrance slit to reflect the rays back through the prism; but this fails because the initial dispersion is annulled during the third and fourth traversals of the prism. This difficulty is easily overcome by using a pair of plane mirrors at right angles to return the radiation through the prism. (The guiding rule is that radiation in successive traversals must not switch from base to apex of the prism or vice versa.)

We thus arrive at the arrangement proposed by Walsh, but in our modification the plane mirrors are placed above the entrance slit instead of alongside (Fig. 2). This arrangement is generally more easily applied to an existing

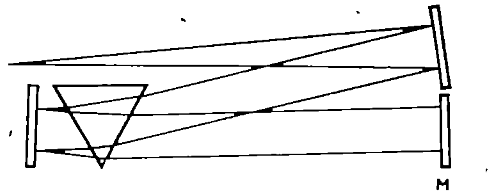

Fig. 1. Littrow system with additional plane mirror *M*, as used by Dr. W. C. Price

spectrometer and has the advantage that the small angle off-axis in a vertical plane (about 1° in the *S*3 spectrometer) tends to reduce the curvature of image already mentioned. In practice, it is unnecessary to make any alteration to the slits, which is a point of some practical importance.

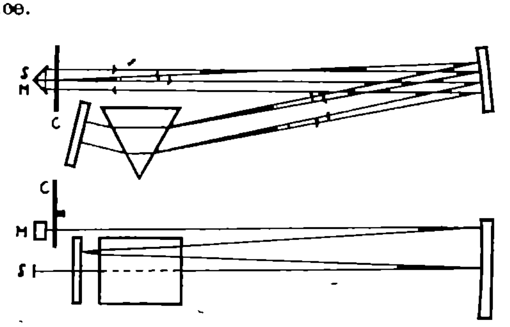

Fig. 2. Plan and elevation illustrating a simple method of converting a single- to a double-monochromator. *S* is the entrance (and exit) slit and *M* a pair of plane mirrors mounted at right angles to each other

The elimination of stray light by chopping after initial dispersion has already been described[2]. In our arrangement the chopper *C* is placed at the position shown in Fig. 2. If the primary spectrum is imagined spread out horizontally across the pair of mirrors, only a small band of wave-lengths will be intercepted by them. If stray light of some other wave-length happens also to fall on these mirrors, it will, of course, be interrupted, but will be separated from the wanted radiation during the further traversals of the prism.

The Xi-Phase and a New Sigma Phase

Six phases with structures isomorphous with the iron – chromium sigma phase have been reported in binary alloys of the transition elements of the first long period[1–3]. In addition, Goldschmidt[4] has shown that the phase FeMo, stable between 1,180° and 1,540° C., has the same structure. In the binary system cobalt – molybdenum, a similar phase Co$_2$Mo$_3$ exists between 1,250° and 1,620° C.[5]; recent work in this Laboratory has shown that Co$_2$Mo$_3$ has a sigma-phase structure. The interplanar spacings of the alloy containing 61 atomic per cent molybdenum are very similar to those of the alloy with 50 atomic per cent FeMo given by Goldschmidt, except that they are slightly smaller, as might be expected when the slightly smaller cobalt atom replaces iron. Multiplying the Co$_2$Mo$_3$ *d*-values by 0·981 gives values which agree well with those for FeCr given by Goldschmidt[4].

As in the iron – molybdenum system, the cobalt – molybdenum sigma-phase has only a limited temperature-range and decomposes peritectoidally to form the xi-phase Co$_7$Mo$_6$, which has a rhombohedral structure stable over a wide range of temperature. It is of interest to compare the occurrence of the sigma- and xi-phase in the binary systems of iron and cobalt with chromium, molybdenum and tungsten respectively. Where the second element is in the same period the only intermediate phase is sigma, which has a wide stability range. With molybdenum both iron and cobalt form a sigma-phase, though this has only a restricted stability-range and decomposes to the xi-phase. In the case of tungsten, the xi-phase only is found. The reason for this transition does not appear to be predominantly a size effect, as there is little difference in the atom sizes of molybdenum and tungsten; it is more probable that it is an electronic one. The xi-phase may thus also be an electron compound, as has been suggested by Sully[6] for the sigma-phase; as is the case with the sigma-phase, the proportions of molybdenum and tungsten are greater in the cobalt phases than in the iron ones.

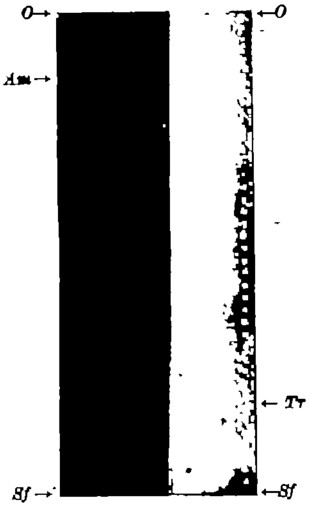
Separation of Enzymes by Paper Chromatography

In a recent publication[1] from this laboratory, a technique for the study of the chromatographic behaviour of enzymes on paper was described. The ease with which enzymes can be readily identifie on the paper chromatogram by the agar-plate metho enabled us to study the chromatographic behaviou of some of the important enzymes. In the course of preliminary experiments with amylases, phosphorylases and phosphatases from various sources we found that some enzymes did not move at al while others moved considerable distances on th paper. This observation prompted us to attemp the separation of enzymes by paper chromatography

Apart from the work of Mitchell, Gordon anc Haskins[2], who report that some separation of adenosine deaminase from amylase has been achieved b their 'chromatopile' method, no really complet separation of enzymes by paper chromatography ha been reported. In a recent note by Wallenfel and Pechmann[3], which appeared after we sen our communication[1] on the technique for the detection of enzymes on paper, the separation of th enzymes of a mould extract by a micro-electrophoreti technique was described. However, by adopting th usual paper chromatographic technique and usin aqueous acetone or sodium chloride or a suitable com



Chromatogram showing the separation of amylase from trypsin: *O*, origin; *Sf*, solvent front; *Am*, amylase; *Tr*, trypsin

ination of these two as developing solvents, we ve been successful in achieving a few good separa- ons of the individual enzymes from mixtures pre- red artificially or obtained from natural sources such mould or tissue extracts.

As a typical example of the separation that can so readily obtained by the paper chromatographic ethod, we reproduce a photograph of the separation amylase from the proteinase, trypsin, present in mmercial trypsin powder (Pfanstiehl Chemical ompany). From the photograph, it can be seen at the amylase shows little or no tendency to ove, whereas trypsin has moved quite a distance om the starting line, and a complete separation f the two enzymes is thus obtained. As it is necessary adhere to our procedure to be able to reproduce ccessfully the above separation, we are giving elow the essential features of our method.

A 2 per cent aqueous solution of commercial ypsin powder was prepared and centrifuged to move the suspended impurities. By means of a icro-pipette (11 μl.) two spots of the enzyme solution ere placed, at an interval of 4 cm., on the starting ne of the filter paper strip (Whatman No. 1, 40 × 8 n.). The chromatogram was run at low tempera- re (0–5° C.), the developing solvent being 50 per nt aqueous acetone containing 1·5 per cent sodium loride. After the solvent front had advanced a stance of 25 cm. from the starting line, the filter per strip was removed from the chromatographic amber and cut into two strips (*A* and *B*) longitudin- ly, to locate the positions of the two enzymes. The sition of the amylase on strip *A* was detected by e method previously described[1]. The elegant and mple method of Wallenfels and Pechman[3] for the tection of proteinases was used for locating the ypsin on the chromatogram. Accordingly, strip *B* s placed on the wetted gelatin side of a 35-mm. né-film strip about 12 in. long. The combination was aced in an incubator at 30° C. and water was sprayed, intervals, on to the paper to keep it moist. After out two hours, which was sufficient for the trypsin liquefy the gelatin, the paper was removed from e film strip. The position of the enzyme, trypsin, the paper is indicated by liquefaction of the latin, resulting in the formation of a clear zone.

It is interesting to note that neither aqueous acetone nor water alone is able to bring about any appreciable movement of trypsin. However, the addition of sodium chloride in concentrations as little as 0·5 per cent to the aqueous acetone or water results in the trypsin moving a considerable distance from the starting line. Further, we have observed that the use of saline solutions enhances the definition of the spots by arresting tailing.

Details of the other separations of enzymes so far achieved by us will be published elsewhere.

Dissociation of Complex Ions in Non-Aqueous Solvents

We have developed recently[1] a method for the micro colorimetric estimation of iron as triphenylmethylarsonium hexathiocyanato ferrate III, $(Ph_3MeAs)_3(Fe(CNS)_6)$, in which this compound was extracted from aqueous solution with *o*-dichlorbenzene in the presence of about seventy equivalents of triphenylmethylarsonium thiocyanate. The orange-red solution had a sharp absorption maximum at 478 mμ (curve *A*), the same wave-length as that observed by Woods and Mellon[2] for the ammonium salt $(NH_4)_3(Fe(CNS)_6)$ in water.

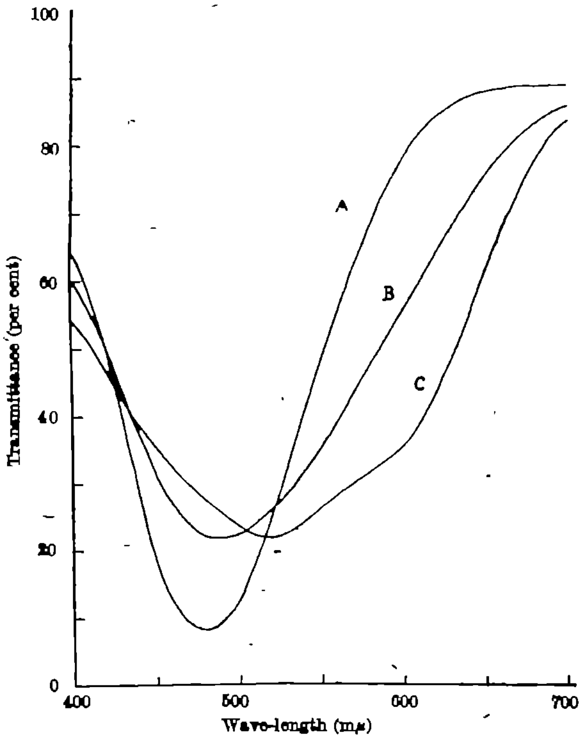
The solid, analytically pure, iron compound could be isolated as a dark red crystalline powder. In *o*-dichlorbenzene this gave a purplish-red solution, with a broad absorption maximum at 488 mμ (curve *B*). The solution became violet when warmed, and reddish when cooled in ice. When the solution was progressively diluted with the solvent and correspondingly thicker cells were used for the determination of the absorption curve, the colour also became violet, developing a sharper absorption maximum at 520 mμ, while in the most dilute solutions a new absorption maximum commenced to develop in the region of 600 mμ (curve *C*). Addition of triphenylmethylarsonium thiocyanate to the violet solutions changed the colour to orange-red. The colour changes are not due to colloidal micelles of different sizes, since a large excess of triphenylmethylarsonium perchlorate caused the violet solutions to become only slightly redder.

The various arsonium compounds used were soluble in a wide variety of non-aqueous solvents such as chloroform and ethylene dichloride in spite of the fact that they are salts. This is undoubtedly due to the large covalent moiety and the existence of ion pairs in the solution.

The colour changes are consistent with the following equilibria, in which arsonium thiocyanate is detached from the complex salt as an ion pair:

$$(Ph_3MeAs)_3(Fe(CNS)_6) \rightleftharpoons (Ph_3MeAs)CNS + (Ph_3MeAs)_2(Fe(CNS)_5) \rightleftharpoons 2(Ph_3MeAs)CNS + (Ph_3MeAs)(Fe(CNS)_4).$$

The triphenylmethylarsonium radical confers solubility in organic solvents on a great number of com-



Curve A: $(Ph_3MeAs)_3(Fe(CNS)_6)$ in o-dichlorbenzene (4·0 μgm. Fe/ml.) + 70 equivalents of $Ph_3MeAsCNS$. 0·5 cm. cell.
Curve B: $(Ph_3MeAs)_3(Fe(CNS)_6)$ in o-dichlorbenzene (4·0 μgm. Fe/ml.). 0·5 cm. cell.
Curve C: $(Ph_3MeAs)_3(Fe(CNS)_6)$ in o-dichlorbenzene (0·5 μgm. Fe/ml.). 4·0 cm. cell.

plex anions such as $FeCl_4'$, BiI_4', $Co(CNS)_4''$, and dissociation of the above type is probably a general phenomenon.

The dissociation of complex salts in water, as pointed out by Bjerrum[3], is complicated by the competition of water molecules for co-ordination positions of the metal, so that complexity constants are not measures of the affinity of the metal for a particular ligand, but of the change in free energy when a solvent molecule is replaced by the ligand. The determination of dissociation constants in solvents such as o-dichlorbenzene or carbon tetrachloride should give a very close evaluation of the true affinities of metals and ligands, as well as the energy of dissociation, since these solvent molecules can be attached by only the weakest of bonds.

Identity of Lespedin with Kæmpferitrin

From the leaves of *Lespedeza cyrtobotrya* Miquel, a deciduous shrub of the natural family Leguminosæ, M. Hasegawa and I isolated a kæmpferol glycoside which we named lespedin[1,2], its structure being shown to be kæmpferol 3,7-dirhamnoside. It has also been isolated from *Celastrus orbiculatus* Thunberg (family Celastraceæ) by M. Kanao and M. Shimokoriyama[3]. When crystallized from water, lespedin had meltin point 195° with or without water of crystallizatio $(3\frac{1}{2}H_2O)$, whereas from ethanol it melted at 234°. I thus appeared to be different from kæmpferitrin melting point 201–203°[4].

Having learnt from Dr. E. C. Bate-Smith that th kæmpferitrin employed in his chromatographi studies was obtained from the original collection o the late Prof. A. G. Perkin (through the courtesy o Dr. E. J. Cross of the Department of Colour Chemistry University of Leeds), I sent a specimen of lespedin t Dr. Bate-Smith in order to have the mixed meltin point of the two glycosides tested. The results h has communicated to me are as follows :

	Softening point	Melting point
Kæmpferitrin	190–192°	194°
Mixture	190–194°	195°
Lespedin	190–194°	195°

Rf values in butanol – acetic acid – water (4 : 1 : 5) and phenol water are for both 0·71. The colours given in ultra-violet light and i ammonia are also identical.

I am satisfied that the identity of lespedin wit kæmpferitrin has been thus established, and the nam 'lespedin' becomes, therefore, redundant.

I wish to thank Dr. T. Swain, who carried out th determinations, and Dr. E. C. Bate-Smith, both o the Low Temperature Research Station, Cambridge for their kindness.

Cholinesterase Activity in the Secretions o the Pancreas of the Dog and Parotid of the Pig

It has been recognized for some time that th pancreas of the dog contains large amounts (pseudo-cholinesterase[1], and the parotid gland of th pig is known to have a much higher cholinesteras activity than other digestive glands in this species Gmsberg *et al.*[2], using a biological method, found the dog's pancreatic juice possessed at least fifteen time the enzyme activity of the blood, but this observation does not so far seem to have been confirmed.

In view of this work and other experiments whic will be reported separately, dog's pancreatic juic secreted in response to different stimuli, was examined for the presence of pseudo-cholinesterase. Th animals were anæsthetized with chloralose before cannulation of the accessory pancreatic duct. Extract of the mucosa of the small intestine and pilocarpin were injected intravenously to stimulate secretior Pseudo-cholinesterase in the juice and in wate homogenates of the gland was estimated manometrically at pH 7·4 with 0·06 *M* acetylcholin perchlorate (B.D.H.) as the substrate. The unit o cholinesterase is defined as the amount of enzym which liberated 1 μl. carbon dioxide/min.

PSEUDO-CHOLINESTERASE ACTIVITY OF DOG'S PANCREATIC JUICE AND PANCREAS

Exp.	Pancreatic juice secreted in response to:			Pancreas (units/gm.)
	Pilocarpine (units/ml.)	Secretin preparation (units/ml.)	Vagal stimulation during secretin flow (units/ml.)	
I	3,240 3,120	420 500	—	1,450
II	1,380 1,450	1,080	1250	2,000
III	2,700 2,870	765 960	1470 1870	2,570

The activity of the pseudo-cholinesterase in the pancreatic secretion of three dogs is shown in the accompanying table.

The results indicate that pseudo-cholinesterase can be present in high concentration in the pancreatic juice of the dog, and in these experiments the amounts appeared to vary according to the stimulus employed, in a manner similar to that of the other enzymes of the juice. In two of the experiments the activity of the secretion was greater than that of the gland, which was removed at the end of the experiment.

Parotid saliva was obtained from two pigs anæsthetized with chloralose, and from two after decerebration under ethyl chloride and ether anæsthesia. Difficulty was experienced in estimating the cholinesterase activity in a satisfactory manner; but it was clear that acetylcholine was hydrolysed at a high rate by the parotid saliva (saliva 30–640 units/ml.; gland 410–670 units/gm.; serum 10 units/ml.).

These preliminary experiments confirm that cholinesterases may be secreted actively by glands[4]. It is not yet possible to assess the significance of their presence in the secretions of digestive glands; but they may have some useful function in the lumen of the gut.

Stimulation of Bile Secretion in Chick Embryos by Cortisone

In some preliminary experiments it was observed that the administration of cortisone to twelve-day old chick embryos caused their gall bladders to become distended and bile to flow prematurely into their intestines. Accordingly a substantial experiment was performed to confirm or deny these preliminary findings, and since there are certain difficulties associated with obtaining either rapid or complete absorption of substances injected into chick embryos, comparatively large doses of cortisone were employed. A dose of 5 mgm. of cortisone ('Cortone acetate') was given to each of sixty White Leghorn chick embryos on the twelfth day of incubation, either by injecting it into the yolk or on to the chorioallantoic membrane. For controls, seventy-five embryos were similarly injected with the same volume of normal saline. The eggs were harvested on the fifteenth day of incubation. The diameters and the lengths of the gall bladders were measured with calipers and their volumes were determined by assuming them to be cylinders. Observations were made in each instance on whether or not bile had reached the intestine to colour it green.

Forty of the sixty embryos receiving cortisone had larger gall bladders than the largest encountered in the control series. The average calculated volume of gall bladders in the cortisone group was 21·1 c.mm. and that of those in the control series 6·9 c.mm. In twenty-eight of the cortisone-treated embryos, bile had reached the intestine to colour it green; this had not occurred in any of the control embryos.

The finding that cortisone can stimulate bile secretion raises the interesting question of how this effect is exerted. With regard to the possibility of the injected cortisone contributing to the formation of bile salts, which in turn produce the effect observed, it should be noted that in our experience the injection of sodium dehydrocholate into twelve-day old chick embryos also stimulates bile secretion; hence the liver at this stage of development is competent to respond to a bile salt stimulus. But since Paschkis, Cantarow, Walkling, Pearlman, Rakoff and Boyle[1] have shown that carbohydrate-active oxysteroids can be recovered from the bile of dogs given adrenal cortical extracts, the possibility of cortisone being excreted as such into bile and, in being excreted, directly stimulating the flow of the medium in which it is contained, should also be considered.

Antivitamin D Factor

Rickets, attended by a reduction in gain of weight, has been frequently reported in weaned lambs grazing on green oat plants and other green feeds during the winter in the South Island of New Zealand[1,2]. The effect is not confined to green feeds grown in this country, since Ewer has demonstrated a rachitogenic effect of green oats grown in England[3].

Previous work in New Zealand[2,4,5] has shown that there is adequate calcium and phosphorus in the rickets-producing plants and that supplementary feeding of calcium and/or phosphorus does not prevent the disease. Rickets was prevented and normal growth-rate restored by a single massive dose of 'Calciferol' (1,000,000 i.u.) given at the commencement of green feed grazing[5], but not by weekly doses of cod liver oil which provided an average of 300 i.u. of vitamin D a day, which is approximately twice the normal daily requirement of young sheep[6]. It was therefore postulated that a rachitogenic factor was present in the green feeds on which ovine rickets occurs. Further support for this hypothesis has been obtained from a recent investigation[7] which suggested that the incidence of solar ultra-violet radiation on sheep grazing green oats was at least as great in an area where rickets occurred as in one where no rickets developed.

A laboratory study was undertaken at this Research Station to investigate the nature and occurrence of the rachitogenic factor in green oats. The white rat was employed as the test animal, and it was kept under the same regime as that developed by Hume *et al.*[8] for the biological assay of vitamin D. By measuring the influence of oat extracts on the ash content of rat bones, the existence of an anti-vitamin D factor has been firmly established. Some of the results are outlined in the accompanying tables.

Table 1 indicates the rachitogenic properties of a chloroform-extract of dried young green oats when given to rats in dilute solution in olive oil. The results summarized in Table 2 indicate the pronounced effect of the oat extract in depressing the bone ash response to vitamin D.

Table 1 (12 rats per group)

Group	Daily dose	Average % ash in dry fat-free femur
1	0·3 gm. olive oil	31·2
2	0·3 gm. solution *X**	27·8

* *X* is a 1 in 30 dilution of the oat extract in olive oil.

Table 2. (7 rats per group)

Group	Daily dose	Average % ash in dry fat-free femur
1	0·3 gm. olive oil containing 0·1 i.u. vitamin D	34·6
2	0·3 gm. solution *X* containing 0·1 i.u. vitamin D	30·1
3	0·3 gm. olive oil containing 0·2 i.u. vitamin D	38·3
4	0·3 gm. solution *X* containing 0·2 i.u. vitamin D	33·1
5	0·3 gm. olive oil containing 0·3 i.u. vitamin D	40·9
6	0·3 gm. solution *X* containing 0·3 i.u. vitamin D	37·0
7	0·3 gm. solution *X* containing 0·4 i.u. vitamin D	38·2

That these results were not due to any factor associated with the oat extract which might reduce the amount of vitamin D absorbed from the gut was demonstrated in another experiment by administering the vitamin subcutaneously and solution *X* orally (Table 3). In each of the four weeks of the trial period, each rat received a subcutaneous dose of 0·1 gm. olive oil containing 2·0 i.u. vitamin D.

Table 3. (7 rats per group)

Group	Daily dose *per os*	Average % ash in dry fat-free femur
1	0·3 gm. olive oil	34·2
2	0·3 gm. solution *X*	27·3

Similar results have been obtained with extracts of young Italian ryegrass, a feed on which winter-grazed hoggets often develop the disease.

Some preliminary work on permanent pasture, on which feed the development of ovine rickets has not so far been reported, has demonstrated that it contains both vitamin D and the antivitamin D factor. Rats on the standard rachitogenic ration developed more severe rickets when dosed with an extract of the young green leaves; but the opposite effect—an increase in the degree of bone calcification—resulted from dosing with an extract of the brown dead leaves. Such dead matter often makes up a considerable proportion of a sample of well-established pasture. The net result of the two effects observed when an extract of the whole pasture sample was given to rats was an increase in bone calcification. That this extract also contained the antivitamin D factor was demonstrated by the fact that a measured amount of vitamin D added to it did not increase the extent of bone calcification by the expected amount. Whether both vitamin D and the antivitamin D factor exist together in varying proportions in both the green and dead material has yet to be determined.

Further studies on the distribution and physiological action of the antivitamin D factor are being made, and work is progressing towards its isolation.

From this investigation, it is apparent that for many materials of plant origin the biologically determined assay figures for vitamin D should be accepted with some reserve, until the physiological action and distribution of the antivitamin D factor has been more fully investigated.

A Further Example of *Kidd* (Jk^a) Hæmagglutinin

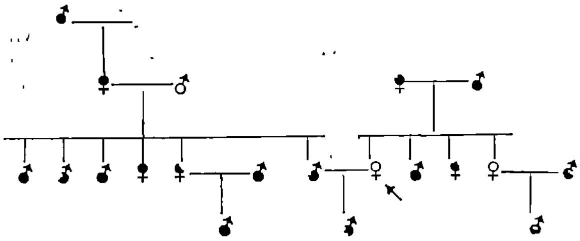
RECENTLY Allen, Diamond and Niedziela[1] reported a previously unidentified blood-group antibody which they termed anti-*Kidd*, or anti-Jk^a. Samples of the serum were most generously sent us by Dr. Allen and Dr. R. R. Race. With these we have identified an antibody of apparently identical specificity.

This antibody was found in the serum of a woman, Mrs. McGimpsey (*McGi*), who is *Rh*-negative, and whose blood was being examined for antibodies as a routine measure during her first pregnancy. She has never had a transfusion. She gave birth to a normal boy on May 17, 1951. On May 29 a direct Coombs test on his blood was negative.

A sample of Mrs. McGimpsey's serum, drawn on February 14 and tested by both the capillary method for saline antibodies and the test-tube for albumen antibodies, did not agglutinate either of two test cells, one being *O*, *MS*, *CDe.cDE*, *Kk*, *Lu*(*a*−), *Jk*(*a*+); the other, *O*, *Ms*, $C^wDe.CDe$, *kk*, *Lu*(*a*−), *Jk*(*a*+). A specimen drawn on April 26 agglutinated both test cells in saline in the capillary, with a doubtful reaction in albumen in the test-tube. It agglutinated eight other *Kidd*-positive cells and did not agglutinate 8 *Kidd*-negatives. This appears adequate proof of its specificity.

The inheritance of the factor defined by the serum *McGi* was investigated in some of the members of the family, as set out in the diagram. Identical reactions were given by anti-*Kidd* and anti-*McGi*.

Inheritance of Jk^a in Family *McGi*



$Jk(a+)$ ♂ ♀; $Jk(a-)$ ♂ ♀; Propositus ↖

Of 146 pregnancy and premarital bloods of groups O and A, 77·4 per cent (113) were agglutinated by *McGi*. Allen *et al.*[1] reported the antigen Jk^a to be "present in the red cells of about 77 per cent of Americans".

Our serum reacts both at room temperature and at 37° C., but better at the latter, by both the capillary method and the test-tube method for saline antibodies.

Temperature Characteristics of the Microflora of Central African Soils

The importance of a knowledge of the effect of temperature on the metabolic activities of the soil microflora can scarcely be questioned, especially in the case of tropical soils. Furthermore, the temperature characteristic of the metabolic activities calculated by the Arrhenius's law:

$$V = \exp(-\mu/RT),$$

where V is the rate of the process, R the gas constant and T the absolute temperature, may be considered as the activation energy of the slowest or 'pacemaking' process in the chain of enzymatic mechanisms[1]. In this case it would be possible to use this method as a kinetic analysis of the slowest enzymatic processes in the metabolism of the soil microflora.

The experimental results presented here report our preliminary findings regarding the order of magnitude of the activation energy calculated from the rate of oxygen uptake at different temperatures. The measurements of oxygen uptake were always made on soils immediately after they had been brought to the laboratory, that is, less than three hours after sampling. Sampling was carried out with a cylindrical soil auger to the depth of 10 cm. About twenty samples were mixed in the field and the composite sample was brought to the laboratory.

The rate of oxygen uptake at temperatures between 28° and 38° was determined on 50-gm. portions of soil (passing a 4-mm. sieve and retained by 1-mm.) with the differential manometer as modified by Lees[2]. Triplicate determinations were made for each temperature. The rate of oxygen uptake of soils recently taken from the field was reasonably constant during the first 30 hr. We have used this value as a measure of the metabolic activity of soil microflora.

TEMPERATURE CHARACTERISTICS AND RATE OF OXYGEN UPTAKE OF CENTRAL AFRICAN SOILS

Soil No.	Oxygen uptake (µl. per hr. per gm. of soil at 28° C.)	Temperature characteristic (µ) cal.
1	5·0	7,500
2	4·0	10,000
3	3·2	7,500
4	2·7	7,000
5	1·1	16,000
6	0·6	16,000

(1) Forest soil under *Cynometra alexandri* Harms; (2) old rubber plantation; (3) forest soil from glade, under second growth; (4) old pasture of *Panicum maximum* and *Digitaria* (soil 1 to 4 on Yangambi reddish-yellow latosol); (5) colluvial sandy soil under young (5–7 years) second-growth forest; (6) the same, four months after felling and burning forest.

The accompanying table presents the observed values for the rate of oxygen uptake at 28° C. and temperature characteristics calculated from the rates at temperatures between 28° and 38° C. The order of magnitude of the values determined for these temperature characteristics agrees well with those given by Crozier for various biological reactions.

It will also be observed that µ values for soil microflora are quite close to the corresponding figures in biological reactions, namely, 16,000, 11,000 and 8,000 cal.

It may be of interest to note that the very sandy soils studied here showed constantly a higher value of µ than the less sandy soils in the same region. Together with other factors, a more pronounced influence of temperature on the microflora of sandy soils might explain the greater difficulty in maintaining the soil organic matter content in light-textured tropical soils.

Work is now in progress on the analysis of the 'pacemaking' process in the metabolic activities of the soil microflora through selective poisoning of characteristic enzymatic systems.

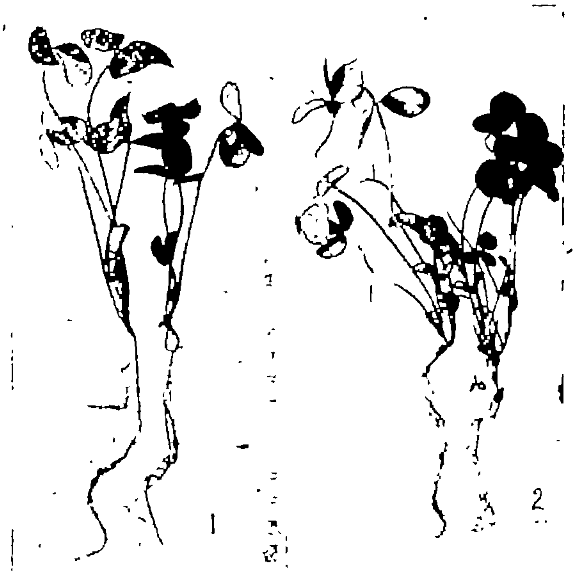
Acid Tolerance in Plants

The failure of certain plant species to thrive on acid soils has been ascribed to an intolerance of the acid conditions.

A number of tree species, such as ash and *Pinus halepensis*, which are usually associated in Nature with alkaline soils, have been the subject of experiments designed to throw light on this supposition. In one such experiment, carried out in pot cultures and in the field, seeds of these trees were sown in the acid soil of Wareham Heath and in this same soil to which compost had been added. The Wareham soil had a pH value of 4–4·5; the compost used had an acid reaction, and the pH value of the soil remained virtually unaltered after addition of the compost. The resulting growth in the untreated Wareham soil was extremely poor, whereas in the composted soil it was excellent, notwithstanding that the reaction of the rooting medium was but little more than pH 4.

The behaviour of a number of agricultural crop plants was also studied, for example, red clover,



Red clover (*Trifolium pratense*) 9 weeks from sowing: (1) soil reaction, *p*H 7; (2) soil reaction, *p*H 4

alsike clover, buckwheat, lucerne, wheat. All these showed good growth under compost treatment in the soil of low *p*H value, quite comparable with that in a compost-treated neutral soil (see accompanying illustration).

From such results it would appear that the limiting factor for growth is not the low *p*H of the soil, since the inhibition to growth can be removed with negligible change in the soil reaction. Addition of a suitable compost is only one way of bringing this about; modification of the soil environment in other ways not involving raising the *p*H may be equally effective when they can be employed, among them establishment of a mycorrhizal relationship previously lacking.

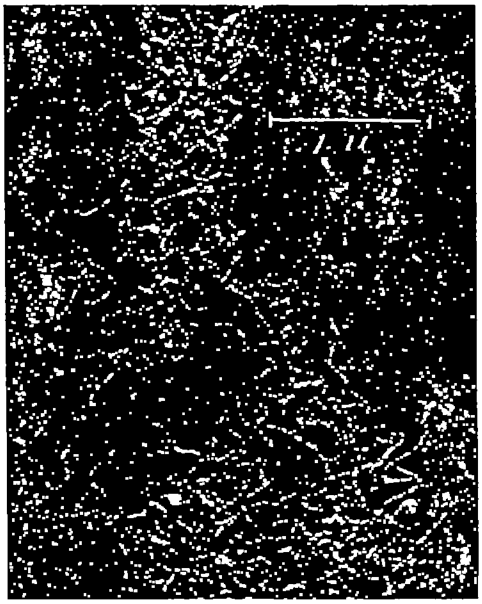
Formation of Silk Fibre by the Silkworm

The silk-producing apparatus of the common silkworm provides a convenient system for the study of several aspects of the synthesis of fibrous proteins. It is particularly useful for the investigation of the transformation from the soluble precursor protein of the gland into the solid, insoluble, fibrous fibroin. The precursor, which may be called 'fibroinogen', accumulates in solution in the silk gland and is converted into the fibre by the disturbances produced during spinning. Certain structural problems have recently been studied by Kratky, Schauenstein and Sekora[1,2], who have described an X-ray pattern characteristic of the soluble precursor, which appears to differ from the well-known pattern of silk fibre. Similar observations have been made by us.

The fibroinogen can be extracted from the silk gland by water and forms at first a slightly turbid solution, which exhibits the usual reactions of soluble proteins[3]. On standing for a few hours, the turbidity increases and the protein separates as a fibrous precipitate. X-ray patterns of the precipitate were found to be similar to those of the ground-up silk fibre (silk 2 according to Kratky *et al.*[1]) and distinct from the carefully dried gland (silk 1)[1]. It appears, then, that the change into the fibrous form can proceed spontaneously in dilute solution without the participation of mechanical stress.

The formation of the fibrous precipitate has been further studied by means of electron microscopy. Examination of the freshly prepared extract dried on collodion films revealed no significant structure, but the aged solution yielded fields, such as that shown in the accompanying electron-micrograph, in which the predominant component is a fine fibril about 100 A. in diameter and up to 3,500 A. in length. The soluble precursor of fibroin thus exhibits the property, already made familiar by electron microscopical studies of fibrin[4] and actin[5,6], of forming fibrils spontaneously in solution.



Since silk fibre is not usually thought to be an aggregation of fine fibrils, a further electron microscopic study was made of fibre spun in the normal way. Natural silk was disintegrated by prolonged tryptic digestion and the fine fibrillar fragments examined electron microscopically. These fragments were found to consist of fine fibrils of a similar diameter to, but greater length than, those shown in the electron-micrograph, and aligned parallel to the length of the fibre, demonstrating that, in the fibre spun in the normal way, there occurs a morphological feature intermediate in size between the molecular level and the whole fibre. Zahn[7] has reported similar observations, and the large spacings found by means of X-rays[8] also point to the existence of large structural elements.

The formation of silk fibre by the extrusion of the viscous contents of the gland or by the stretching of the gland appears closely analogous to the process of making artificial fibres, and suggests that the polypeptide chains of the soluble corpuscular molecule unfold and from this state are drawn into parallel strands by stretching[9]. On the other hand, the spontaneous appearance of fibrils in solution seems more simply explained as being due to an unsymmetrical aggregation of the particles of the soluble form without the occurrence of unfolding. There is evidence that this is the case with actin and fibrin. This theory, which may be referred to as 'the linear aggregation theory', could also account for the existence of discrete fibrils and the large lateral spacings.

Since the formation of an unsymmetrical aggregate may prove the characteristic step in fibre building, the conditions of its formation and other aspects of the theory are being investigated. The initiation of such aggregation may rest with purely colloidal forces, as will be shown in future publications from this laboratory. Afterwards, in the linear aggregate, short-range forces could ensure the orientation of the component molecules (or complexes) and thus lead to a fibril oriented at the molecular level, as is required to account for the fibre-type X-ray pattern. The mechanical stresses set up during spinning probably merely orient the preformed fibrils. Further research is necessary to elucidate the nature of the modification in small-scale molecular structure which also seems to accompany fibril formation.

Effect of Hosts on the Egg Coloration of the Parasite *Bracon gelechiæ* Ashmead (Braconidæ)

Salt[1] has reviewed the literature on the effect of hosts upon their insect parasites. Knight[2] found that a carotinoid pigment of the bug *Perillus* was obtained from its prey, the potato beetle (*Leptinotarsa decemlineata*). Toumanoff[3] discovered that in *Dixippus morosus* the pigmentation may be transmitted by the female to the eggs and so to the offspring. I have not come across any record of the effect of hosts upon the pigmentation of the eggs of the parasite.

Bracon (*Microbracon*) *gelechiæ* Ashm. is an ectoparasite of the larva of the potato tuber moth, *Gnorimoschema operculella* Zell. In my laboratory experiments I found the Braconid to be polyphagous, parasitizing caterpillars of various moths, for example, the Pyralids *Scirpophaga nivella* F., *Argyria sticticraspis* Hamp. and *Chilo zonellus* S., and the Noctuids *Plusia orichalcea* F., *Sesamia inferens* W. and *Earias insulana* B. The parasite was reared on the caterpillars of each of these hosts up to the fifth generation. Except in the eggs of the parasite reared on *P. orichalcea* and *E. insulana*, no marked change in the pigmentation of the egg of the parasite was observed. The eggs laid by the females of the second generation reared on the above two species showed a slight tinge of yellow pigmentation; the pigmentation of the eggs produced by the females of each subsequent generation gradually increases, and ultimately the eggs produced by the females of the fifth generation thus reared are distinctly yellow in colour. This coloration is more intense in the eggs of the females of the fifth generation reared on *Earias insulana*. It is interesting to note that the coloration of the cocoons of the parasites of the fifth generation is yellow. It is worth mention also that when the adult Braconids thus obtained from coloured eggs are again reared on the natural host, *G. operculella*, it is found that the yellow pigmentation is markedly present in the eggs laid by the females of the next generation; but the yellow pigmentation of the eggs laid by the females of each of the subsequent generation decreases in stages. Up to the fourth generation the pigmentation, though insignificant, still persists, and is at last lost in the eggs laid by the females of the fifth generation. The normal white colour of the eggs is thus restored.

In the present case, therefore, the coloration of the eggs of the parasite is clearly a character which is induced by the host, through an article of food, and hence an important factor is environment.

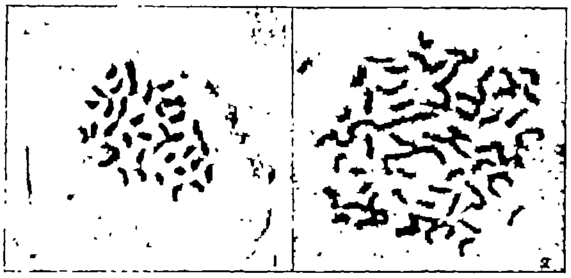
Chromosome Numbers of *Cerastium* Species

Since my publication of chromosome counts of *Cerastium* species in 1950[1], five further counts have been made, two of British material, *C. arvense* L. and *C. viscosum* L., and three of Continental material, *C. dichotomum* L., *C. tomentosum* L., and *C. alpinum* L. The results for these species are shown in the accompanying table.

Species	2n	Original source of material
C. arvense L	72	Isle of Man
C. viscosum L.	72	Malham Tarn, Yorkshire
C dichotomum L.	38	Not known. Seed obtained from Botanika Zahrada University Karlovy, Prague
C. tomentosum L.	72	Not known. Cultivated garden plant
C alpinum L.	c. 144	Abisko, Sweden

The counts for the British material, *C. viscosum* L. and *C. arvense* L., both $2n = 72$, agree with counts made by Rohweder[2], who used Continental material, though I have also counted $2n = 38$ for *C. arvense* L. collected in the Alps[1].

Of the Continental material, *C. dichotomum* L., $2n = 38$ (Fig. 1), has not previously been counted. *C. tomentosum* L., $2n = 72$ (Fig. 2), has also been counted by Rohweder[2], who, however, obtained $2n = 38$. It would appear that this species, like *C. arvense* L., is a complex one containing plants with at least two different chromosome numbers, namely, $2n = 38$ and $2n = 72$. It is hoped that crossing experiments will help to elucidate these two species.



Somatic metaphase plate of (1) *C. dichotomum* L., showing 38 chromosomes; (2) *C. tomentosum* L., showing 72 chromosomes. × 1,500

The count of $2n = 144$ for *C. alpinum* L. is only an approximation, as an accurate count has not yet been possible. The number certainly exceeded $2n = 108$ and $2n = 72$, which I[1], and other workers[2-5], have previously recorded for *C. alpinum* L. It would appear that this species contains a polyploid series, $2n = 72$, $2n = 108$, $2n = 144$.

Statistical Methods in Anthropology

There has been a lively discussion, in *Nature*[1] and elsewhere[2], on the classification of recent fossil finds in South Africa. Prof. S. Zuckerman has rightly stressed the need for basing such decisions on statistical tests. But his findings have been at odds with those based on classical comparisons; so that anthropologists must now be in doubt whether their science has, indeed, anything to learn from statistics.

This unhappy result can be traced to the piecemeal tests which have hitherto been used. A bone or a tooth is a unit; it is not a discrete assembly of independent measurements. To compare its single variates one by one, as Ashton and Zuckerman have done[3], is both inconclusive and misleading. Inconclusive, because nothing is decided when it is shown that, say, the height of an incisor lies in the range of heights of gorilla incisors, and the breadth lies in the range of breadths of chimpanzee incisors—a state of affairs which may well be characteristic of a species different from both; and misleading, because tests based on dimensions which are correlated are themselves not independent, and little is gained by accumulating them.

The right statistical method must treat the set of variates as a single coherent matrix; and this is, in fact, the technique of multivariate analysis. Consider, for example, four measurements (in millimetres) of a lower milk canine: x_1 the height, x_2 the maximum anterior–posterior length of the upper half, x_3 the maximum breadth of the upper half, and x_4 the maximum anterior–posterior length at the level of the basal cingulum. Also consider the problem, in the first place, of discriminating between two species—say, chimpanzee and man. Then the measurements should be combined in a single discriminating function,

$$X = a_1x_1 + a_2x_2 + a_3x_3 + a_4x_4, \qquad (1)$$

where the constants a_1, a_2, a_3, a_4 are to be calculated from the averages, the variations, and the correlations, of the measurements within both species.

The discriminant we obtain in this way, using the measurements of forty human and forty-four chimpanzee milk canines, is

$$X = x_1 - 7 \cdot 49x_2 + 2 \cdot 34x_3 + 4 \cdot 70x_4, \qquad (2)$$

and this has on the average the value

$$X = +\ 17 \cdot 6 \text{ for the chimpanzee,}$$

and has the average value

$$X = -\ 5 \cdot 0 \text{ for man.}$$

The standard deviation of X is $2 \cdot 45$; so that the range of X, taken at $2\frac{1}{2}$ times the standard deviation, is $6 \cdot 1$ on either side of the average.

In order to classify a tooth, which is supposed to be either a human or chimpanzee lower milk canine, x_1, x_2, x_3, x_4 are measured in millimetres, and the measurements inserted in the discriminant function (2) above. If the result lies between $+23 \cdot 7$ and $+11 \cdot 5$ the tooth is chimpanzee; if between $+1 \cdot 1$ and $-11 \cdot 1$ it is human. For all the eighty-four teeth the measurements of which we have had, this test is decisive. The supposition that a tooth belongs to one of these two groups is at least strengthened by the fact that its value of X falls into one of the two ranges.

As an application, we have calculated the value of the discriminant function given by (2) for the Kromdraai and the Taungs milk canines found in South Africa. The values are $-2 \cdot 6$ and $-7 \cdot 9$ respectively. They demonstrate conclusively that these teeth do not belong to the chimpanzee group. More than this, they fall precisely in the human range. It would be wrong on this ground alone to conclude positively that they are human teeth; for the measurements might, for example, be matched on an object which turns out to be a pebble or a fake. But within the limits of the present comparison, the statistical evidence is that these teeth belong to the human family.

These methods of discrimination need not be confined to a choice between two alternatives. The technique of multivariate analysis makes it possible to construct functions to discriminate at one time between a number of species, and we hope elsewhere to construct such functions for human, chimpanzee, gorilla and orang-utan teeth. These functions can, we believe, have an important place in biological classification, for which indeed they were first designed. They show that the methods of modern statistics are not alien to anthropology, but are capable of assessing a fossil or a limb as a unit, and not as a haphazard jumble of piecemeal measurements.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, November 5

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. W. V. Lewis: "Glacier Investigation by Tunnelling".

University of London (at the London School of Economics and Political Science, Houghton Street, Aldwych, London, W.C.2), at 5 p.m.—Prof. W. J. M. Mackenzie: "Science in the Study of Administration".*

Society of Engineers (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. L. H. J. Hersch: "Oilfield Operations".

Society of Chemical Industry (joint meeting of the Food, Agriculture and Microbiology Groups and the London Section, at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Dr. H. R. Dawson: "The Cultivation and Propagation of Baker's Yeast".

Pharmaceutical Society (at 17 Bloomsbury Square, London, W.C.1), at 7.30 p.m.—Mr. H. G. Rolfe: "Pharmaceutical Industry in America".

Tuesday, November 6

Chadwick Public Lecture (in the Sir Edward Meyerstein Lecture Theatre, Westminster Medical School, 17 Horseferry Road, London, S.W.1), at 2.30 p.m.—Dr. A. T. Doig: "The Principles of Prevention of Industrial Diseases".*

Society of Chemical Industry, Crop Production Panel of the Agriculture Group (in the Chemistry Lecture Theatre, Royal College of Science, South Kensington, London, S.W.7), at 2.30 p.m.—Symposium on "The Selective Toxicity of 2-4, D and MCPA in Wheat, Oats and Barley".

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5 p.m.—Prof. J. M. Mackintosh: "Trends of Opinion about the Public Health, 1901–1951, 1, The New Age" (Heath Clark Lecture).* (Further Lectures on November 8, 13, 15 and 19.)

Institution of Chemical Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Prof. D. M. Newitt, F.R.S., and Mr. M. Coleman: "The Mechanism of the Drying of Solids with Special Reference to China Clay".

Institution of Electrical Engineers, Measurements Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "Measurements Involved in the Testing of Protective Equipment" (to be opened by Mr. H. S. Petch).

Royal Anthropological Institute (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Huxley Memorial Lecture.

University of London (at King's College, Strand, London, W.C.2), at 5.30 p.m.—Dr. H. E. Rose: "The Measurement of Particle Size in Very Fine Powders".* (Further Lectures on November 13, 20 and 27.)

Sheffield Metallurgical Association (at the Grand Hotel, Sheffield), at 7 p.m.—Mr. A. A. Smales: "Radio Chemistry as an Aid to the Analytical Chemist".

Wednesday, November 7

Association of Applied Biologists (in the Mining Lecture Theatre, Imperial College of Science and Technology, Prince Consort Road, London, S.W.7), at 11 a.m.—Discussion on "Photography in Applied Biology".*

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific Papers.

Society of Public Analysts and Other Analytical Chemists (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Scientific Papers.

Thursday, November 8

Royal Society (at Burlington House, Piccadilly, London, W.1), 4.30 p.m.—Sir Charles Ellis, F.R.S.: "Science in the Coal Industry".

Mineralogical Society (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific Papers.

Institution of Electrical Engineers (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. T. Kilvington, Mr. F. J. M. Laver and Mr. H. Stanesby: "The London–Birmingham Television-Cable System".

Textile Institute, Yorkshire Section (joint meeting with the West Riding Section of the Society of Dyers and Colourists, at the Great Northern Victoria Hotel, Bradford) at 7.15 p.m.—Dr. F. Happey: "Synthetic and Natural Polypeptides".

University of London (at Wye College, Wye, Kent), at 8.15 p.m.—Dr. H. P. Donald: "Facts and Fallacies in Livestock Breeding".*

Friday, November 9

Royal Sanitary Institute (in the Guildhall, Cambridge), at 10 a.m.—Papers on "Three Approaches to Man's Welfare" (Mr. D. W. Bottom: "Improving the Environment"; Dr. C. G. Eastwood: "Caring for Body and Mind"; Prof. A. Leslie Banks: "Research and the Wider Issues").

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Scientific Papers.

University of London (at Charing Cross Hospital Medical School, Chandos Street, London, W.C.2), at 5 p.m.—Prof. E. Wolff: "Sex Differentiation in Vertebrates".*

Institution of Mechanical Engineers (joint meeting with the Hydraulics Group, at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Mr. G. A. Wauchope and Mr. H. P. Humphreys: "The Design of Large Pumping Installations for Low and Medium Heads".

North-East Coast Institution of Engineers and Shipbuilders (at the Literary and Philosophical Society, Newcastle-upon-Tyne), at 6.15 p.m.—Prof. J. F. Baker: "Shortcomings of Structural Analysis" (Andrew Laing Lecture).

Institute of Economic Engineering (at the George Hotel, Church Lane, Kingsbury, London, N.W.9), at 7 p.m.—Mr. Winston Rodgers: "Pre-determined Motion Times".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. C. D. Darlington, F.R.S.: "The Two Theories of Heredity".

Saturday, November 10

Biochemical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 11.15 a.m.—Symposium on "Metabolism and Function of Nervous Tissue".

British Psychological Society (in the Eugenics Theatre, University College, Gower Street, London, W.C.1), at 2.30 p.m.—Dr. H. A. Innes: "Fundamental Research in Human Relations".

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Sir Harry Lindsay: "The Museum and Education".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant (with a degree in engineering or equivalent qualification) in the Department of Mechanical and Civil Engineering—The Registrar, Technical College, Infirmary Road, Chesterfield, Derbyshire (November 10).

Assistant (Grade B) for Mechanical Engineering at the Swansea Technical College—The Director of Education, Education Department, The Guildhall, Swansea (November 10).

Assistant (Grade B) in Inorganic Chemistry at the Constantine Technical College—The Director of Education, Education Offices, Woodlands Road, Middlesbrough (November 10).

Assistant Experimental Officers (with a degree in engineering or physics, or equivalent) in the Horticultural Department—The Secretary, National Institute of Agricultural Engineering, Wrest Park, Silsoe, Beds (November 10).

Demonstrator in Chemistry—The Registrar, Technical College, Sunderland (November 10).

Head of the Department of Metallurgy, a Senior Lecturer in Metallurgy, and a Lecturer in the Department of Engineering, County Technical College, Wednesbury—The Director of Education, Department F.E., County Education Offices, Stafford (November 10).

Lecturer in Electronics and Telecommunications, and a Teacher of Mathematics, at the Coventry Technical College—The Director of Education, Council House, Coventry (November 10).

Lecturer in Mechanical Engineering, and an Assistant Lecturer (Grade A) in Mechanical Engineering, at the South Shields Marine and Technical College—The Director of Education, Town Hall, South Shields (November 10).

Principal of the Bury Technical Institute—The Director of Education, Education Offices, Bury (November 10).

Scientific Officer (Ref. R/A) for research and development work on mechanical engineering problems, a Senior Scientific Officer (Ref. R/O1) for development to prototype stage of mechanical mechanisms of an original nature, a Scientific Officer (Ref. R/C2) for work on combustion and heat transfer problems, and a Scientific Officer (Ref. A/T2) to work on engineering problems—The Secretary, National Institute of Agricultural Engineering, Wrest Park, Silsoe, Beds, quoting the appropriate Ref. No. (November 10).

Teacher (honours graduate in chemistry) in Chemistry—The Principal, Harris Institute, Preston (November 10).

Research Assistant in the Department of Geography, to assist in a project of research in agricultural geography—The Secretary, University College, Gower Street, London, W.C.1 (November 12).

Physicist or Physical Chemist (Scientist II) to take part in laboratory scale investigations into crushing, screening and briquetting of coal, at the Central Research Establishment, Stoke Orchard, Cheltenham—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/384 (November 14).

Research Officer (with honours degree in physics or physical chemistry) to carry out work on physical properties of gelatin gels and solutions—The Director, British Gelatine and Glue Research Association, 2a Dalmeny Road, London, N.7 (November 14).

Engineer and Manager of the Water Company—The Engineer and Manager, Gas and Water Company, Hartlepool, endorsed 'Engineer and Manager' (November 15).

Lecturer in Mechanical Engineering—The Registrar, King's College, Newcastle-upon-Tyne (November 17).

Assistant Lecturer in Geology (with qualifications in palæontology)—The Registrars, The University, Manchester (November 24).

Postgraduate Studentship in Physics—The Registrar, University College, Leicester (November 24).

Head of the Physics Department at the Radiotherapy Centre—The Secretary, War Memorial Hospital, Scunthorpe, Lincs. (November 26).

Research Officer (Physicist) in the Division of Food Preservation and Transport, Sydney—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting No. 3609 (November 24).

WATER ENGINEER AND MANAGER OF THE LEICESTER WATER UNDERTAKING—The Town Clerk, Town Hall, Leicester, endorsed 'Water Engineer' (November 24).

ASSISTANT DIRECTOR PUBLIC HEALTH BACTERIOLOGICAL LABORATORY (University of Melbourne)—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 30).

HUGH WOOD MEMORIAL FELLOWSHIP IN MINING—The Registrar, The University, Leeds 2 (November 30).

LECTURERS (2, specialists in medical protozoology and medical entomology) IN PARASITOLOGY at the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (November 30).

PROFESSOR OF PHILOSOPHY at the University of Natal, Pietermaritzburg—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 30).

SENIOR LECTURER IN SOCIOLOGY AND SOCIAL WORK at the University of Natal, Durban—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 30).

LECTURER IN MINING SUBJECTS, and a LECTURER IN SCIENCE, at the Wrexham Technical College—The Director of Education, Education Offices, Ruthin, Denbighshire (November 30)

RESEARCH ASSISTANT IN NUMERICAL ANALYSIS in the Department of Applied Mathematics—The Registrar, The University, Liverpool (December 1).

SENIOR LECTURER IN PHYSICAL CHEMISTRY in the University of Tasmania and Hobart Technical College—The Agent-General for Tasmania, 457 Strand, London, W.C.2, or the Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (Hobart, December 1).

STATISTICIANS (5, main grade) in the Civil Service—The Secretary, Civil Service Commission, Burlington Gardens, London, W.1, quoting No. 4093/51 (December 6).

RESEARCH ASSISTANT (graduate in physics) for laboratory work connected with Papermaking in the Department of Textile Chemistry—The Registrar, College of Technology, Manchester 1 (December 12).

PROFESSIONAL ENGINEERS in many Departments of the Civil Service for a wide variety of engineering duties—The Secretary, Civil Service Commission, Trinidad House, Old Burlington Street, London, W.1, quoting S.86/51 (December 31)

REGIUS PROFESSOR OF CIVIL ENGINEERING AND MECHANICS in the University of Glasgow—The Private Secretary to the Secretary of State for Scotland, St Andrew's House, Edinburgh 1 (December 31).

CHIEF SOIL CONSERVATOR, and SOIL CONSERVATORS or JUNIOR SOIL CONSERVATORS, to the Otago Catchment Board—The Secretary, Otago Catchment Board, P.O. Box 858, Dunedin, New Zealand (January 18).

LECTURER IN PIGMENTS in the Department of Colour Chemistry and Dyeing—The Registrar, The University, Leeds 2 (January 19).

H.M. INSPECTORS—The SECRETARY (Inspectors' Section), Ministry of Education, Curzon Street, London, W.1 (January 31).

POSTGRADUATE FELLOWSHIPS (34) for research in pure chemistry and physics tenable in the National Research Council Laboratories at Ottawa, and POSTGRADUATE FELLOWSHIPS (5) in biochemistry, microbiology and related fields tenable in the Prairie Regional Laboratory at the University of Saskatchewan, Saskatoon—The Secretary, Laboratories Awards Committee, National Research Council, Ottawa, Canada, or The Chief Scientific Liaison Officer, National Research Council of Canada, Africa House, Kingsway, London, W.C.2 (Ottawa, February 15).

ASSISTANT LECTURER IN MATHEMATICS—The Registrar, The University, Nottingham.

CHEMICAL ENGINEER for investigations on various aspects of whiting manufacture, including drying processes, classification of powders by wet and dry processes, and general handling of suspensions and powders—The Director of Research, Research Council of the British Whiting Federation, 245 Ampthill Road, Bedford.

CHEMIST, general or analytical (with a good honours degree in chemistry, a sound knowledge of analytical chemistry and research and administrative experience), a RUBBER TECHNOLOGIST (with a wide experience in rubber technology and some experience of research and development work), and a COLLOID CHEMIST (with a good honours degree and research experience in surface or colloid chemistry) to undertake fundamental research on natural latex, at the Rubber Research Institute of Malaya, Kuala Lumpur—The Secretary, London Advisory Committee for Rubber Research (Ceylon and Malaya), Imperial Institute, South Kensington, London, S.W.7.

CHEMIST at Risley, to advise plant design engineers on the metallurgical aspect of their work, etc., and a CHEMIST at Springfields Factory, Salwick, Preston, to supervise the work of a team engaged on the development of powder metallurgy processes—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs, stating post applied for.

CHEMISTS (Principal Scientific Officer grade) (with a first- or second-class honours degree or equivalent in chemistry, with many years responsible research experience in modern methods of analysis of inorganic materials, including microchemical methods) at a Ministry of Supply research and development establishment near London—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting F.640/51A.

CHEMISTS (Scientific Officer grade) at the Ministry of Supply factory at Capenhurst, Chester, for research into the detailed behaviour of inorganic systems and their surfaces (the work may involve electronic diffraction and X-Ray techniques as well as conventional chemical qualification)—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs.

CURATOR (with an honours degree in archæology, with some anthropological training) IN THE DEPARTMENT OF MUSEUMS, Malaya—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. No. 2744C/1/51.

ENGINEER (with degree or equivalent in engineering) to assist in development work connected with concrete vibrators, etc., at research laboratories of the Cement and Concrete Association, Wexham Springs, Slough—The Secretary, British Cast Concrete Federation, 17 Amherst Road, Ealing, London, W.13.

EXECUTIVE ENGINEER IN THE PUBLIC WORKS DEPARTMENT, Northern Rhodesia, for general civil engineering duties—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting 27322/115.

EXPERIMENTAL OFFICER at Springfields Factory, Salwick, Preston, to assist in large-scale development work on processes or reduction of metals and treatment of residues—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs.

EXPERIMENTAL OFFICERS at the Atomic Research Establishment, Harwell, for work in Physics, Electronics and Scientific Computing (Ref. A.309/51A/BA), and Chemistry (other than Organic Chemistry), Chemical Engineering and Metallurgy (Ref. F.777/51A/BA)—The Ministry of Labour and National Service, Technical and Scientific Register (K), York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No.

GRADUATE IN PHYSICS (with a bias towards engineering) to undertake research work in the unexplored field of glasshouse heating and ventilation—The Head of the Garden Research Department, John Innes Horticultural Institution, Bayfordbury, Hertford, Herts.

HEAD OF THE CHEMICAL ENGINEERING SECTION, and a PLANT PHYSIOLOGIST to direct and undertake fundamental biochemical investigations with a view to the ultimate development of mass culture techniques for the lesser known marine algæ of potential industrial value—The Secretary, Institute of Seaweed Research, Inveresk, Midlothian.

PHYSICIST to carry out research on the performance of photographic lenses—(Applications), Technical Optics Section, Physics Department, Imperial College of Science and Technology, South Kensington, London, S.W.7.

PHYSICIST, and a PHYSICAL CHEMIST (with first- or second-class honours degree; some postgraduate experience is desirable)—The Director, British Paper and Board Industry Research Association, St. Winifred's Laboratories, Welcomes Road, Kenley, Surrey.

RESEARCH ASSISTANT (graduate in chemistry) IN THE DEPARTMENT OF CHEMICAL ENGINEERING AND APPLIED CHEMISTRY, to carry out investigations on ignition and flame propagation in gases—The Registrar, Imperial College of Science and Technology, South Kensington, London, S.W.7.

SENIOR PLANT PATHOLOGIST (Senior Principal Scientific Officer) at the West African Cocoa Research Institute, Gold Coast—The Under-Secretary of State, Colonial Office, Research Department, Sanctuary Buildings, Great Smith Street, London, S.W.1.

SENIOR PRINCIPAL SCIENTIFIC OFFICER (veterinary research) to undertake direction of protozoological, epidemiological and trypanosomiasis research, a SENIOR SCIENTIFIC OFFICER (veterinary research) to undertake research in animal trypanosomiasis, a SCIENTIFIC OFFICER (veterinary research) to undertake research in animal trypanosomiasis, a PROTOZOOLOGIST to undertake studies of tyrpanosomes and trypanosomiasis, and MEDICAL RESEARCH OFFICERS (2) for research into human trypanosomiasis and epidemiology, at the Central Trypanosomiasis Institute, Sukulu, Uganda—The Under-Secretary of State, Research Department, Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1.

TEACHER (professorial grade) OF PHARMACOLOGY at the Lady Hardinge Medical College, New Delhi—The Secretary (Division 5A), Ministry of Health, Savile Row, London, W.1.

INTERNATIONAL INSTITUTIONS

IN a book published a few months ago*, Mr. T. Besterman makes a praiseworthy attempt to set forth the activities of the United Nations Educational, Scientific and Cultural Organization and the ideas behind them. In a series of readable chapters he indicates how the Organization is working in the fields of education, science, the social sciences and humanities, and the conditions which determine its success or failure, and what has already been achieved in regard to reconstruction, mass-information and the exchange of persons. He establishes very clearly that there is room for such an Organization in the world to-day; but though in his final chapter his criticisms and conclusions deal with some important factors in Unesco's development, he does not quite succeed in grappling with some of the essential issues. His book, for all its merits, leaves the impression of over-optimism and of a head a little too much in the air.

A striking corrective to this little book and a wholesome stimulus to constructive thinking about the real and wider issues is a report which has been issued, partly under the imprimatur of Unesco itself and partly under that of the International Institute of Administrative Sciences, Brussels. Entitled "National Administration and International Organization"†, this report describes an inquiry conducted jointly by the two bodies with the view of improving international co-operation and the operation of the United Nations, the Specialized Agencies and similar bodies. It is open to criticism in that the inquiry was limited in scope and not sufficiently representative. The fourteen governments selected for the inquiry, although varying in size and responsibilities, are politically and culturally too homogeneous. The difficulties in the way of international collaboration and the conditions essential to make any body like Unesco effective would have been even more apparent had the Middle East, Far Eastern and backward countries been included. Outside Europe and America, India is the only country represented, and, in spite of the cultural diversity, its system of government is also founded on democratic principles.

Whether in India and in some of the other countries the conditions exist under which democratic principles can be served and a democracy function is another question, and this survey shows very clearly what an important bearing it has on international organization and co-operation. There cannot be, as this study shows, any standard pattern for administering the relations of national governments with international institutions: political traditions, the structure of organization, national resources and national interests vary too widely, though it is true that every government has something to learn from the administrative experience of other governments, particularly where their situations are comparable. Disregarding considerations of national policy, however, the study emphasizes that the level of international administration, in a society of co-operating sovereign States, can rise no higher than the level of national administration in those States. Deficiencies in national administration, whether they are due to personal failures or to the inherent unsuitability of the national organization to its social and economic conditions, are at once reflected on the international plane.

---

* Unesco: Peace in the Minds of Men. By Theodore Besterman. Pp. xi+134+12 plates. (London: Methuen and Co., Ltd., 1951.) 10s. 6d. net.

† National Administration and International Organization. a Comparative Survey of Fourteen Countries. Report of an Inquiry conducted jointly by the International Institute of Administrative Sciences and Unesco. Pp. 78. (Paris: Unesco; London: H.M. Stationery Office, 1951.) 150 francs; 8s.; 50 cents.

This is a point which is commonly overlooked in discussing international organization and plans for international co-operation, for example, in regard to technical assistance to the under-developed areas. It is brought out as strongly by this inquiry as in Mr. Besterman's book, and it is worth noting that it was equally emphasized by Dr. Herbert Greene and other speakers at the discussion, at the British Association meeting in Edinburgh last August, on surveys of under-developed areas. It provides the main reason for the concern of the scientific or technical expert with the subject of this inquiry and with the theme of Mr. Besterman's book.

The two main difficulties in international collaboration which are brought out by these publications are, first, the tendency of numerous governments to express different views in different places on related international problems; and secondly, the failure of all too many governments to discharge promptly and effectively their substantive obligations as participants in a co-operative international system. The first not only creates confusion but may also affect the soundness of the plans which are formulated. The second, however, could make the formulation and execution of plans a complete waste of time. It is the growing disregard for international obligations and the unilateral repudiation of negotiated agreements that is the most disturbing feature of to-day. If it is unchecked, it can halt all schemes for economic and technical assistance to backward countries. Technicians and scientific advisers cannot work confidently and effectively apart from some rule of law and guarantee of stability, nor indeed will it be possible to recruit them for such work. If they cannot be recruited, then the programme stops. In this connexion, the challenge which present events in Persia and Egypt thus presents to international institutions does not appear to have received the attention it demands.

The inquiry carried out by Unesco and the International Institute of Administrative Sciences, moreover, brings out that while the major responsibility for consistent, prompt and effective observance of international obligations by national governments rests with these governments themselves, such matters are no longer the affair of Foreign Offices and professional diplomats alone. A wide range of government departments and of technical and professional advisers may be involved, and what was once regarded as a matter of foreign relations is not easily distinguished from domestic affairs. For a government to pursue a reasonably stable and consistent course in its foreign relations, close and continuous liaison between the legislative and the executive is essential. Similarly, in democratic countries—and elsewhere—governments are now obliged to heed demands emanating from public opinion and from a variety of interested groups which find expression in various ways. As a corollary, the ethical standards of a government in its international relations are unlikely to be much above that of the standards of the community it governs.

It is this point, rather than the minor suggestions which are made in this report for improving administrative organization and methods of organization, that deserves attention at the moment. It is not suggested that any of the fourteen reporting countries covered by the inquiry was satisfied with the existing state of affairs, or that further improvements might not result from greater attention to the recruitment, selection and training of staff. This also is secondary, and though Mr. Besterman, too, directs attention to the unfortunate consequences of excessive turnover of staff and to the difficulties which can arise once any considerations other than that of professional competence enter into the selection of staff for a post, the dominant factor in efficient working and in securing an efficient international secretariat is the standard of co-operation and interest shown by the participating countries. Deficiencies in that respect cannot be offset by any scale of salaries designed to compensate for genuine expatriation and the speculative character of such employment. Indeed, it should be remembered that too lavish an endowment of such posts with diplomatic and taxation privileges may fail to attract staff of the integrity desired and also provoke criticism which may militate against co-operation. The personal character which is as essential as administrative ability for such posts will not be forthcoming, whatever the terms of remuneration, unless the work is manifestly seen to be worth while and enjoys the respect of professional bodies as well as of governments.

To strike the right balance here is admittedly not easy. Whether or not this is a contributory factor, Unesco at least scarcely seems to enjoy the standing among professional associations that many of its activities would warrant. Mr. Besterman's little book, by contributing to a wider understanding of what Unesco is doing, should in a modest way assist in increasing that repute. By and large, so far as science is concerned, Unesco's reputation and influence must depend on the extent to which the value of its projects becomes known to the scientific world through its links with the international unions and other professional bodies. In Great Britain the newsprint position is a severe handicap in making the work of Unesco better known, but even so the position is unlikely to be remedied by the circulation of Unesco's own publications. Indeed, on Mr. Besterman's own showing, contraction might be a wiser policy than expansion here, if appropriate arrangements could be made with existing publishing bodies.

For all the valuable work that Unesco has undoubtedly done in its five years or so to meet some of the world's needs in the field of education, culture and learning, and to strengthen some of the international bodies already working in those fields, it is difficult to regard the immediate situation with confidence, still less optimism. As Sir John Maud recently pointed out, Unesco itself has now established a growing number of personal and professional relations between the men who are chiefly responsible for educational and scientific progress in their own countries. Outside Unesco, the programme of technical assistance to the backward areas would seem to offer a most encouraging vista of international co-operation and understanding.

All this, however, is overshadowed by the failure of member States of the United Nations to keep faith and to honour obligations into which they have entered. The very facts, on which this inquiry into national administration and international organization rightly insists, that distinct boundaries between domestic and international problems no longer exist, and that the conduct of foreign affairs must be regarded as an inseparable part of the larger problem of organization for the conduct of national affairs as a whole, make it essential that there should be some common standards of value among the participants in any form of international organization. Without such standards, misunderstandings, frustrations and acerbity, leading ultimately to anarchy, are inevitable.

It cannot be too strongly insisted that good faith and the observance of negotiated agreements and obligations are a *sine qua non*, and in their absence minor improvements in administrative procedure are irrelevant. In the limited sphere of Unesco, the irresponsible disregard of obligations which Mr. Besterman notes is made more invidious by the fact that rather more than half Unesco's income comes from the United States and the United Kingdom; of the other members, only France and China contribute even 7 per cent. In spite of this, all members have equal voting rights. Mr. Besterman rightly points out that reconsideration of this egalitarian principle is unavoidable if certain nations and groups of nations continue to manifest the irresponsibility in voting and in observing obligations which have marked recent years. In view, moreover, of what is happening in the wider context of the United Nations, it may well be asked if the time has not already come for the United Kingdom to consider whether it can continue its own contribution to such organizations on the present scale, or whether it should not concentrate the resources it can spare for the furtherance of international understanding in more limited organizations where there exists a standard of goodwill and honesty of purpose which make effective co-operation possible.

The latest annual report of the Secretary-General of the United Nations points to the need for realistic thinking here. One of the functions of the United Nations is to provide a common ground on which antagonists can meet to resolve their differences. It was proposed as an organization affording each nation a forum in which it could argue its case as an equal. Only the conduct of the members of the Organization can show that Mr. Trygve Lie is right in maintaining that the Organization's function as a forum need not frustrate its function as policeman, and the evidence since his report was written is very much the other way. If the Security Council and other organs of the United Nations continue to condone the flouting of international agreements and of the authority of international institutions by governments pledged by their membership of the United Nations to observe a code of good behaviour, it may well be asked whether it is worth persisting in membership. Whatever the immediate outcome of the recent unilateral repudiation of agreements in the Near East, fresh thought must be given by Great Britain to the implications of such incidents before the country is committed to further large obligations in any international organization where there can no longer be presupposed the essential basis of good faith and respect for such obligations by all contracting parties.

ANTHROPOLOGY AND SOCIAL STUDIES

The Foundations of Social Anthropology

By Prof. S. F. Nadel. Pp. xi+426. (London: Cohen and West, Ltd., 1951.) 25*s.* net.

Society

An Introductory Analysis. By Prof. R. M. MacIver and Prof. Charles H. Page. Pp. xix+698. (London: Macmillan and Co., Ltd., 1950.) 25*s.* net.

SOCIOLOGY and social anthropology are closely allied subjects. Apart from this, there is no real reason for comparing these two books. Profs. R. M. MacIver and Charles H. Page have produced a summary of present sociological knowledge. They progress from one aspect to the next, until the whole panorama of their subject is displayed. The book has the merits of all good encyclopædic work, and will be invaluable as a bibliography and as a teacher's book of reference. At the same time, it inevitably carries the flatness and finality of a text-book.

Prof. S. F. Nadel, on the other hand, has written, not a summary of anthropological knowledge, but an inquiry into the nature of sociological knowledge. As he says, social anthropologists have had a tendency to apologize about their subject. The societies they study have often no written records, the language may never have been studied, and the environment and customs are strange; in face of these difficulties, their techniques are necessarily 'tentative' and their concepts 'fluid'. For these reasons he has undertaken now a book about method, rather than one about results (with which he considers anthropologists have hitherto been too exclusively concerned). His training in logic qualifies him well for a work which aims at defining the place of anthropology among the sciences, by linking the 'study of man' with the whole universe of scientific knowledge.

Prof. Nadel considers that such a wealth of ethnographical data has been assembled in the past three decades that an "era of systematization" is now due. These data he speaks of as raw material awaiting the "fuller synthesis" which will "lead to valid generalizations on primitive culture and society". His view that the time for such a synthesis is near is shared by others who also exhibit his interest in methodology, but its truth may be questioned.

Even after studying his argument one is forced to doubt whether the ethnographer's material, however systematized, is yet capable of yielding a single valid generalization. It is to be hoped that at some later stage he will himself publish much more fully the results of his own valuable research among tribes in Nigeria and the Sudan. Only a few anthropologists have justified the claim that Prof. Nadel makes for their research, as distinct from traditional sociology, that it is both more intensive and comprehensive. Few have remained sufficiently long in any single society to produce a study that goes beyond the broad outlines which give a misleading impression of sameness from one society to another. The few who have achieved the highest standards unfortunately stand alone as experts on widely separated regions. In short, comparative work within a given region on the basis of modern intensive study has scarcely begun.

Prof. Nadel rightly claims that its subject-matter provides for social anthropology data which differ from those of sociology; instead of considering class-structure or heredity and environment, it is faced with problems of taboo, clan exogamy or totemism. But original data have not, in fact, produced new sociological theories. A personal interest in methodology may have tempted him to hope that systematization will one day yield generalizations about society, but one may equally well argue against him that in sociology the process has worked usually in the opposite direction. The fact-collecting and systematization directed by the Victorian anthropologists were stimulated by hypotheses about social evolution and cultural diffusion. Similarly, in the United States to-day a vast amount of research has been undertaken to test current theories about the relation between culture and personality. In this subject, at least, it seems that theories produce facts and not vice versa.

Since the 1920's, when Malinowski raised the standard of field-work, and Prof. A. R. Radcliffe-Browne set a sociological scaffolding around ethnology, the stimulus they gave to social anthropology has to some extent evaporated. The history of philosophy shows that a branch of learning develops a dominant preoccupation with methodology only in its relatively sterile periods, and certainly many exponents of social anthropology seem deeply concerned with its status and methods. It must be admitted that no major speculative theory has appeared which compares with those which inspired the Victorian anthropologists.

As a minor criticism of the scope of Prof. Nadel's work, it may be remarked that a book of this size gives unduly little space to the serious problem of how there can be reliable knowledge of social phenomena for an outside observer whose language and categories of thought belong to an alien culture. This is only sketchily touched upon in a dozen pages on "Observation and Description".

In certain branches of sociology the need for the stimulus of sweeping sociological theories does not seem to be felt. The impetus of most of its research derives ultimately from the moral conscience, the concern to remedy pressing social evils. The relation between academic knowledge and social reform is generally close. Anthropologists, on the other hand, find it difficult, though some try strenuously, to justify their work on strictly practical grounds. The scope and character of their studies in alien societies make them, indeed, more wary than enthusiastic for social change. If it is called into play at all, their moral conscience tends to find itself opposing schemes for social advance.

The book by Profs. MacIver and Page, in spite of proper magisterial detachment, reflects in its subject-matter the characteristic preoccupation with social problems. It is divided into three parts. After only a few pages of definition, the first plunges into the relations between the individual and society, co-operation and conflict, society and environment, and then on to social control and the problem of moral liberty. Part 2 covers the major forms of social structure, and Part 3 social change. The book is admirable as a summary, but is not intended as a criticism of current trends of thought. It is in the nature of a good text-book to draw on pre-suppositions which are already a little out of date, and this one is faithful in reflecting the prejudice and weakness as well as the strength of contemporary sociology. This is particularly noticeable in the unconscious bias against religious organization in the section on conflict between religion and morals, which is more significant in view of the later chapter on "Evolution of the Church as a Social Form". This section is based on assumptions which have been challenged by important modern publications on primitive religion and magic.

MARY DOUGLAS

COLLOID SCIENCE

Colloid Science

Edited by Prof. H. R. Kruyt. Vol. 2: Reversible Systems. Pp. xix+753. (Amsterdam and New York: Elsevier Publishing Co., Ltd.; London: Cleaver-Hume Press, Ltd., 1949.) 77*s.* 6*d.*

IT must be said first that this is not a text-book on colloids; rather it is a record of the work of the Dutch school under the distinguished leadership of Prof. H. R. Kruyt, and the volume suffers from the limitations thereby imposed. This factor will probably be unimportant in Volume 1; but in the present volume it is serious.

The writers, faced by the almost insurmountable difficulties of finding a logical order of dealing with colloids and their properties, have chosen the thermodynamic classification into reversible and irreversible. Volume 2 deals with the former, which includes macromolecules and association micellar colloids. Macromolecules receive 211 pages, gels and solid macromolecules 193, while coacervation with related topics occupies 248. Micellar colloids are compressed into 37 pages, of which about half is taken up by coacervation. Thus 40 per cent of the book is of little interest to the majority of colloid chemists. It is stated in the introduction that the work on coacervation is included because of its inaccessibility to English and American readers; it should, however, have been published as a separate monograph. It seems most unfortunate that the name 'coacervation' has been extended to the clear case of macromolecule-solvent systems separating into two layers without clear proof that Bungenburg de Jong's 'coacervation' is the same phenomenon. In this book, the two cases are discussed in separate sections.

The book is a collective work to which the contributors are: R. Houwink, J. J. Hermans, P. H. Hermans, J. Overbeck, Bungenburg de Jong and H. L. Booy. The editing is very good; in this subject, in which basic ideas and nomenclature current in the literature are often far from clear, as in the word 'colloid' itself, or even grossly misleading as 'emulsoid', the need for clear definition is paramount. This has been achieved in the book under review, though how far it is due to editing and how far to clear thinking by the Dutch workers over a number of years cannot be said ; whichever it is, the credit is due to Prof. Kruyt. It should be read word by word more than once. Its particular merits are that it stimulates and disciplines. It is suitable for advanced students and research workers interested in colloids, and should find a place wherever colloids are studied seriously.

It will be most interesting to see in Volume 1 how the authors deal with irreversible colloids, for which the thermodynamic approach to stability is so much less useful than the kinetic. There is a real danger to-day that research workers dealing with macromolecular colloids may be lamentably ignorant of the other types. This is due in part to the common habit of young workers of regarding investigations more than about ten years old as obsolete ; and in part to nomenclature and the need for revision of the treatment of the classical colloids. It is as well to remember that there is one basic and fundamental property only common to all types, namely, the large size of the free kinetic unit of the solute. Can one imagine a book on ordinary solutions which did not mention the colligative properties ? We must recognize that although many of the properties, especially their commercially useful ones, depend upon the interaction between particles, the single molecule, whatever its size, still remains the fundamental chemical unit, and it can still be studied only in ideal solution, that is, at a dilution such that mutual interaction effects are reduced to zero. There is nothing new in this situation : exactly the same applies to metals. The confusion really arises from the word 'colloid'. Is there such a thing, or are there only colloidal solutions ? The answer is, of course, that the colloidal state is a state of dispersion, and that there is therefore no such thing as a 'colloid'.

A. S. C. LAWRENCE

FREE-LIVING NEMATODES

Soil and Freshwater Nematodes

A Monograph. By Dr. T. Goodey. Pp. xxvi+390. (London : Methuen and Co., Ltd. ; New York : John Wiley and Sons, Inc., 1951.) 45*s*. net.

THIS monograph by Dr. Goodey will be welcomed not only by specialists but also by the general zoologist. To the latter the nematodes are a somewhat troublesome group : they are superficially so similar, there are so many of them, they are so widespread and the relevant literature scattered. Dr. Goodey previously published a useful volume on the nematodes parasitic on plants which gave access to these forms ; but there are still a large number commonly found living free in the soil and in fresh water. It is to these that the present book is devoted. Many of the plant parasites are also to be found in the soil and so are included, but only as soil inhabitants, since details concerning their relationship with the host plant are to be found in the other volume.

The systematic arrangement to a considerable extent follows that of Chitwood and Chitwood, starting with the two main sub-classes Phasmidia and Aphasmidia. This division rests, in the main, on the presence or absence or reduction of the curious, paired, possibly sensory organs, termed phasmids, situated in the lateral areas of the caudal region. The introduction includes a useful section on the technique of handling nematodes and an account of their structure sufficient to follow the systematic definitions that follow. A uniform treatment is adopted throughout and the descending classificatory groups are clearly defined down to genera. For each genus, in addition to the definition, there is a more detailed description of one species, accompanied by diagrams sufficient for accurate diagnosis. The species generally chosen is the genotype ; but, where this is unsuitable, for example, if it is marine, another typical, more accessible species is described.

The illustrations are comprised in 190 figures in the text, but as each figure contains three, four or five diagrams a very large amount of information is conveyed. Most of these line block illustrations are excellent, but a few suggest they have been reproduced from worn or inadequately inked blocks. In the review copy Figs. 53 and 98 are examples. The treatment does not extend to descriptions of species, but under each genus is a list of the recognized species accompanied by a brief reference to the original description. As a number of species in a genus may be large—*Dorylaimus* contains 195 species and ten additional varieties—treatment of the individual species would require a number of volumes the size of the present one and would prove too unwieldy and expensive to have a wide appeal. At the conclusion of the account of each genus is a paragraph on its bionomics, and in looking through these the reader is at once struck by the large gaps in many genera. In some genera, as in *Aphelenchoides*, where a good deal is known, a letter after the specific name indicates whether it is an obligate plant parasite, saprophagous, connected with insects or predatory. Thus a great deal of information is conveyed in a concise manner.

In fact, to the reviewer, conciseness is the most outstanding feature of this book ; indeed, it is remarkable how much information is contained within its 390 pages. The last part of the book, apart from an adequate index, is a list of references. Here again this is a selective bibliography, and the further references that can be obtained easily from Stiles and Hassall's catalogue or the *Zoological Record* are not included unless for a special purpose.

The author is to be congratulated on producing a volume that, like its predecessor, will be an essential to all interested, however remotely, in the field it covers.

C. H. O'DONOGHUE

RECENT DEVELOPMENTS IN METAL PHYSICS

Progress in Metal Physics, 2

Edited by Dr. Bruce Chalmers. Pp. viii+213+23 plates. (London : Butterworths Scientific Publications, Ltd., 1950.) 45*s*.

THE appearance of the second volume of this series is most welcome, and all interested in the science of metals will find much of value. In the reviewer's opinion the editor has been wise in refusing to make the book a report on the progress in any one period, and in again presenting a series of self-contained articles most of which can be read with profit by an honours graduate in metallurgy, physics or chemistry with no specialized knowledge of the subjects concerned. The standard of writing varies, and some articles would have profited if the authors had submitted their manuscripts for criticism, not only by experts in the subject but also by the general reader for whom the book is intended.

The first paper, by H. Lipson, on "Order–Disorder Changes in Alloys", is a model of its kind, beautifully written and illustrated, and arranged so that the reader's attention is continually directed to the important points. The next review, by I. I. Betcherman on "Rate Processes in Physical Metallurgy", is less satisfactory. It covers a wide range, but some of the writing is too superficial to be of real value, while the description of the work of Frederickson and Eyring is confusing; there are also several misleading legends to the figures. The third paper, by W. Boas and J. K. Mackenzie on "Anisotropy in Metals", is excellent, and the description of a wide range of properties should be most stimulating to those who are prepared to cope with the rather formal introduction to the ideas of the mathematics of the vector–vector relations. The paper by H. G. Warrington, on "Developments in Magnesium Alloys", seems rather out of place, since much of it is concerned with technology rather than with fundamental metal physics. The atomic radii given on p. 137 are not the quantities usually known by this name, and it is strange to find no reference to the work of G. V. Raynor on magnesium alloys.

The last fifty pages are devoted to a symposium on polygonization, introduced by a paper by R. W. Cahn on "Internal Strains and Recrystallization". This is stimulating and suggestive, but in some parts it is rather premature and, as in the later papers, the description suffers from the fact that the author accepts the dislocation hypothesis so completely that what are really interpretations in terms of the hypothesis sometimes appear as statements of fact. It must not be forgotten that, however great the promise of the hypothesis, it is supported by little direct experimental evidence, and has led to the prediction of relatively few facts before their discovery. The paper by A. Guinier and J. Tennevin, on "Polygonization", is interesting and beautifully written, while the final contribution, by C. Crussard, F. Aubertin, B. Jaoul and G. Wyon, describes "Polygonization in Strongly Deformed Metals". The volume thus covers a wide range and should be read by all concerned with the physics of metals.

W. Hume-Rothery

CANCER FOR THE LAYMAN

Cancer

Where we Stand. By Prof. Sidney Russ. Pp. xv+192+16 plates. (London, New York and Toronto: Oxford University Press, 1950.) 10*s*. 6*d*. net.

We are all interested in the subject of cancer. There are few whose families and friends have not included someone who has died of cancer. Malignant disease has a terrible reputation. Nevertheless, a substantial proportion of people suffering from many types of cancer have been completely cured by means of surgery or radiotherapy or by the combined use of both these methods of treatment. Most intelligent people know that with early diagnosis and prompt surgical treatment, many forms of cancer can be successfully eradicated. Few, however, appreciate the achievements of radiotherapy. The statistics published during the past few years show that for new cases of cancer of all types treated by radiation, and excluding the almost completely curable basal cell carcinoma, the corrected survival-rate is almost exactly one-third after five years and one-quarter after ten years. For similar cases treated twenty-five years ago, the five-year survival-rate was about one-eighth. It seems reasonable to assume that one of the most important factors responsible for this improvement has been the application of physics to radiotherapy.

Prof. Sidney Russ is one of the leaders of the group of British physicists who have contributed so much to these applications of physics to the treatment of cancer. It is evident that for many years he has thought about the problem of cancer from many angles. The study of cancer is still outside the main stream of biological teaching, and it is difficult for the intelligent layman to acquire an objective elementary knowledge of this field. With a sense of duty, Prof. Russ has attempted the almost impossible task of writing a simple and accurate account of the present position with regard to the scientific study and medical diagnosis and treatment of cancer. In my opinion he has succeeded admirably.

The book starts with an account of the nature of cancer and theories of its origin. The second chapter is a useful discussion of the prevalence of cancer and of the public attitude to malignant disease. The results of the surgical and radiological treatment of cancer are set out clearly in a later chapter. I think that the best part of the book is the discussion of the results of treatment and the logical insistence on early diagnosis and prompt treatment with a minimum of delay.

A great deal of information about radiological physics and many biological subjects such as cancer throughout the animal kingdom and occupational cancer are skilfully introduced. The chapter entitled "Historical Notes on Cancer and its Treatment" is interesting and should convince anyone of the folly of reliance upon treatment by quacks. Appendix 3, at the end of the book, includes a very simple statement of what should be known about cancer, with much good advice.

The chapter on research in cancer, together with the short chapter on palliative chemotherapy, introduces the general reader to some of the important lines of thought in these fields.

The last chapter is entitled "Cancer in the Future". In it, Prof. Russ puts forward a number of suggestions for the advancement of the treatment of cancer, with which I think there is general agreement. I would like to suggest that the knowledge that present methods of treatment are much more effective than is commonly realized should encourage people to seek medical advice without delay. It is, of course, essential that greater hospital facilities for the diagnosis and treatment of patients with cancer should be provided in order to utilize more fully for the benefit of the individual patients the best methods of treatment available at the present time.

Of the suggestions made by Prof. Russ for the further encouragement of experimental cancer research, I think that special mention should be made of the need for greater inducement to research workers outside the purely medical sciences to participate in this field.

This little book is well produced and has interesting illustrations. A number of references are given in the text. I should like to suggest that, in a subsequent edition, a limited bibliography would add to its value.

J. S. Mitchell

Biology of *Drosophila*

Edited by M. Demerec. Pp. x+632. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1950.) 80*s*. net.

A BOOK with this title ought to be a summary of the behaviour, feeding, mating and larval habits of all the numerous species of *Drosophila*, seen in relation to insect life as a whole, and to the special roles of this genus as an introduced pest into temperate climates and as a laboratory animal. This one is not. Only the last chapter, "Collection and Laboratory Culture" by Warren P. Spencer, concerns the insect as a whole, and contains much practical advice to all who need to trap flies and rear them in the laboratory. The other six chapters, "Normal Spermatogenesis" by Kenneth W. Cooper, "Early Embryology" by B. P. Sonnenblick, "Histogenesis, Organogenesis and Differentiation in the Embryo" by D. F. Poulson, "Postembryonic Development" by Dietrich Bodenstein, "External Morphology of the Adult" by G. F. Ferris and "Internal Anatomy and Histology" by Albert Miller, deal only with bits of the animal, and of course refer almost exclusively to *D. melanogaster*.

The real purpose of this symposium is to provide a handbook of what is considered 'normal' in the morphology, histology, embryology and post-embryonic development of *D. melanogaster*, a standard of reference by which the vast amount of experimental work on this fly can be assessed. Deciding what is 'normal' is necessarily a strongly subjective process; but the work is extremely well documented and includes some references up to 1947. The numerous illustrations, including many excellent photomicrographs, are very clearly lettered, and the account of post-embryonic development includes a chronological table of events as they take place in the 'normal' fly at 25° C. G. F. Ferris's section on external morphology presents a personal point of view that diverges considerably from generally accepted views, especially in trying to avoid such apparent discontinuities as exist between the mouth-hooks of the larva and the mouthparts of the imago.

The geneticist, the embryologist and the insect morphologist will all find this symposium a valuable guide into collateral fields of study, while the general entomologist, and especially the dipterist, will welcome such an exhaustive study of one species. It is a pity about the title. H. Oldroyd

Introduction to Electron Optics

The Production, Propagation and Focusing of Electron Beams. By V. E. Cosslett. Second edition. Pp. xvi+294+8 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1950.) 27*s*. 6*d*. net.

THE second edition of Dr. Cosslett's well-known book is a photographic reprint from the first edition, with some mis-statements and misprints corrected. The text thus differs little from the original, but a series of notes on more recent work has been added, as well as some numerical examples on the more theoretical chapters. The first edition appeared before many of the advances made during the Second World War were made public. It is therefore regrettable that the final third of the book, dealing with applications of electron optics in research and industry, has not been rewritten to include the progress made in electron microscopy, particle acceleration and the generation and amplification of centimetre waves. However, the book is written mainly for students and those commencing research work, and it must be judged in this light. The first edition was always highly regarded as being an excellent introductory text, and the new edition should maintain this good reputation.

Orkney

By Hugh Marwick. (County Books Series.) Pp. viii+287+49 plates. (London: Robert Hale, Ltd., 1951.) 15*s*. net.

NO part of Scotland is richer in prehistoric remains than the islands of the Orkney group. Both habitations and burial places are numerous, and all seem to begin in Neolithic times. These matters are described and discussed in this book, and well illustrated by photographic plates. But the volume is not only archæological. All aspects of the islands are treated, though the natural history perhaps has least notice. There are, however, other books on these aspects. Agriculture gets adequate notice. The islanders depend almost wholly on this for their prosperity, their exports being eggs and cattle, and some lobsters. There are no industries, though the manufacture of tweed is beginning. Population has been falling for the past hundred years, and only twenty-seven of the sixty islands have any inhabitants; and several have only one farm or a lighthouse. The book has an adequate map.

The Land of Britain

Its Use and Misuse. By L. Dudley Stamp. Second edition. Pp. viii+507. (London, New York and Toronto: Longmans, Green and Co., Ltd., in conjunction with Geographical Publications, Ltd., 1950.) 45*s*. net.

THIS valuable book, first published in 1948, has now been re-issued in what the publishers describe as a second edition; little if any change, however, seems to have been made in the text. The bibliography is unaltered and stops at 1946, although some valuable reports and books published since that date might well have found a place. Also there still remain the puzzling discrepancies between the official statistics of land utilization in England and Wales as published by the Ministry of Agriculture and those as quoted on p. 481: up to 1939 the figures agree with those of the Ministry, but for 1940–46 they do not, and no explanation is given. Also the figures stop at 1946, but the later ones, which are very interesting, are available. A completed table brought up to date would have been very helpful; in no other readily accessible volume are these important statistics assembled on one page as they are here.

The need for a re-issue shows how widely the book has been appreciated. Nowhere else can the student find so full and authoritative an account of the land of Britain or so good a summary of the labours of the devoted band of workers who carried out the classical Land Utilization Survey on which it is based.

The original Survey was carried out in 1931 and 1932, and, since then, British agriculture has undergone profound changes. Would it be possible to repeat the Survey now that twenty years have elapsed, so as to have a full record of these changes? The information would be invaluable for those whose task it is to direct the new agriculture, and there still remain a sufficient number of the old workers to ensure that the results would be comparable with those of the 1931 Survey. E. John Russell

AGRICULTURAL RESEARCH IN THE GROUNDNUT SCHEME, 1947–51*

By Dr. A. H. BUNTING

Recently Chief Scientific Officer of the Overseas Food Corporation

THE Overseas Food Corporation has recently decided, following the curtailment of the scope of its operations in Tanganyika, to reduce the scale and to revise the organization of its agricultural research services. As a preliminary to this reorganization the post of chief scientific officer has been abolished, and steps are under consideration by which part of the work formerly conducted by the Corporation may be transferred to other agencies. It seems appropriate at this juncture to record in outline the objects and the results of the work up to the present time.

The Scientific Department of the Corporation was founded by my appointment as chief scientific officer on January 30, 1947. Its task has been to assemble the technical knowledge necessary for the successful establishment of systems of mechanized crop production in the Corporation's areas of Tanganyika. To carry out this task the Department has developed a considerable organization for field investigations and for supporting laboratory work.

The European research staff in the crop season of 1950–51, including agricultural trainees attached to the Department, numbered thirty-eight, of whom eighteen were academically qualified. This staff, aided by African assistants trained in the Department, operated three fully mechanized experimental stations, ranging in size from 800 to 1,000 acres, at Kongwa, Urambo and Namanga, near Nachingwea, in the Central, Western and Southern Provinces of Tanganyika respectively. The headquarters of the Department, including the statistical and chemical laboratories, are at Kongwa.

Questions arising from the work of the Department which require a more fundamental attack have been passed, wherever possible, to the East African Agriculture and Forestry Research Organization for study. Collaboration has also been developed with the official agricultural and related technical services in Tanganyika, and in practically all other territories of tropical Africa, in Australia, in the United States and in many other countries, and notable help has been received from university departments and official and commercial research organizations in the United Kingdom. The chief scientific officer was a member of the East African delegation to the African Regional Scientific Conference in Johannesburg in October 1949.

The research programme has been based on a broad general exploration and assessment of the edaphic, environmental and biological factors operative in the three regions. This has included the assembly of meteorological data, with special reference to rainfall in the Kongwa area, the generalized pedological study of soils, particularly in the Kongwa and Southern Province areas, and extensive botanical and entomological collections of species of economic interest.

Soil Studies

A fairly clear qualitative idea has been gained of the fertilizer needs of crops on the more important soil types of the three areas. In general, it has been established that it is necessary to use phosphate for all crops, with nitrogen, usually as a top dressing, for sorghum, maize and other non-legumes. The quantitative study of fertilizer needs has more recently received closer attention, and it is clear that on some soils, at least, about 0·2 cwt. P_2O_5 per acre is sufficient to give an economically satisfactory response, although the economically optimal levels of application have not yet been precisely determined. Residual effects of phosphatic and organic manures, which have been found in field experiments, are now receiving closer attention, and work has begun on the effect of grasses on the soil nitrogen cycle (including the removal of nitrogen by leaching), with special reference to the possible role of grass courses in the conservation of soil nitrogen. In collaboration with members of the staffs of the Empire Cotton Growing Corporation and of the Tanganyika Department of Agriculture an initial examination has recently been completed which strongly suggests that *Tridax repens*, a common weed at Ukiriguru, in the Lake province of Tanganyika, plays an important part in the mobilization of soil phosphate. In 1951, an experiment on the nutrition of tobacco showed that quality in Virginia flue-cured tobacco at Urambo is dominated by the balance of nitrogen and potash. This result may have a profound effect on the future of tobacco production in Tanganyika, since it appears to be possible, by the correct use of fertilizers, to produce a tobacco free from the 'tang' which has been so characteristic and adverse a feature of Tanganyika tobacco in the past.

Crop Research

A systematic programme of crop introduction, from tropical and subtropical countries in all continents, has provided much valuable material, most of which was new to Tanganyika and in many cases to East Africa as a whole. The groundnut collection includes about 250 varieties, from which new, long-season types with seed dormancy are being developed to facilitate groundnut production in wetter areas, where harvesting of short-season types has at present frequently to be undertaken before the end of the rains, and to aid in the fight against the rosette virus disease of the crop (see below). The sorghum collection contains more than 160 varieties and has been the basis for all commercial production of this crop by the Corporation so far. The ideal type of sorghum for mechanized production in Tanganyika appears to be a stout-stemmed, rust-resistant dwarf, with a well-exserted head of shallu type, small glumes and a light-coloured giant grain of the Kafaru or Kaura type, developing a horny peripheral layer at maturity as a protection against storage pests.

---

* Based on an address to the Fifth Annual Conference of the Scientific Department, Overseas Food Corporation, held at Kongwa, Tanganyika, August 18–20.

All the necessary characters for such a variety are represented in the sorghum collection.

Safflower was introduced to East Africa, probably for the first time, by the Corporation, and may yet become a useful combine crop for the drier areas. It may even find a place as a late-planted crop in the wetter areas on suitable sites, extending the peak periods of planting and harvesting.

The soya bean collection contains about seventy varieties. Certain of these have transformed the prospects of this crop in Tanganyika, as a result of the recognition of the limiting effect of equatorial day-lengths on growth and yield in all varieties of soya in use in East Africa hitherto. The standard South African, Rhodesian and American types of soya bean, when exposed to equatorial day-lengths, receive the flowering stimulus at a very early stage and give small plants and poor yields. For success in Tanganyika, especially in mechanized production, a soya variety must be sufficiently tolerant of short days to produce considerable vegetative growth before accepting the flowering stimulus. Six such varieties obtained from equatorial or subequatorial territories are now in the possession of the Department. Four of them, in a formal trial at Urambo in 1950–51, yielded 1,500–1,600 lb. per acre, against 100–900 lb. for the other types tested.

Much attention has been given to maize and also to minor crops, and particular interest is attached to recent work at Urambo on the mechanized production of paddy rice, and to the pilot scale development of Turkish tobacco production at Kongwa.

The agronomic programme has led to elementary investigations in crop physiology at points of economic importance. Studies of root distribution in soils and subsoils have added to the understanding of crop behaviour at Kongwa and Urambo. In 1950 a preliminary investigation, using the techniques of growth analysis, was carried out on the development of the groundnut crop. It showed, *inter alia*, that in the short-season variety, Natal Common, about one-third of the final yield of kernels is laid down in the last fortnight of the life of the crop. This result has been confirmed in 1951 by harvesting experiments.

Soil Management

In the field of soil management, a study has been made over three seasons of moisture relationships in Kongwa soils. This has shown that while no moisture accumulates at Kongwa under continuous cropping, considerable reserves can be built up by bare fallowing in a dry farming rotation. The gypsum-block technique is being used in these investigations to follow variations in the amount and distribution of available soil moisture. At the same time field experiments have indicated the very considerable advantages to be expected from bare fallowing: in the case of groundnuts 300 lb. additional kernels per acre have been obtained as a result of bare fallowing, the yield being raised from 700 to 1,000 lb. per acre. The crucial importance of weed control, particularly in the earlier stages of the life of crops, has also been shown at Kongwa.

A simple ridge and furrow system of ploughing, set out on the contour, has been evolved at Urambo as an addition to normal soil conservation practice, in an attempt to control surface wash and to reduce ponding and excess moisture in seed beds. Experience in the abnormally wet season of 1950–51 at Urambo has been very encouraging, and the method is now under trial in French West Africa as well as in Tanganyika.

It has been demonstrated that the avoidance of soil compaction, which was once regarded in some circles as a major and practically insoluble problem, is entirely a question of intelligent soil management.

On general matters of cropping technique, much has been learnt about seed dressings, seed-bed preparation, sowing rates and methods, time and method of harvesting and related matters. A few long-term experiments, and several two-year trials, have been devoted to the examination of crop sequences and rotations.

Plant Protection

The Department's pathologists and entomologists have maintained continuous surveys of crop diseases and pests. All actual or potential biological enemies so far encountered have been identified, with the aid of workers in Britain and elsewhere, and a working knowledge of the bionomics of the more important organisms, leading already in a few cases to methods of control, has been obtained. Crown rot of groundnuts has so far received more attention than any other disease, because of the fear that it might be cumulative. This has not proved to be the case. Advances have been made towards the control of *Sclerotium* foot rot and *Cercospora* leaf spot of groundnuts. In the entomological field *Calidea dregei* has for the first time been followed through its annual cycle and the study of its control by means of insecticides has begun. Stem borers of sorghum and maize represent a most serious problem: their biology at Kongwa is now fairly well understood; but their control is difficult and would seem to require attention on an East African scale. Studies of the pollination of sunflowers have confirmed the view that the natural populations of pollinators are inadequate for large-scale production of the crop, and have increased our knowledge of the behaviour of wild bees in Tanganyika.

The outstanding piece of work in the plant protection field has been the study of the rosette disease of groundnuts and its aphid vector, *Aphis craccivora*. An adequate picture of the field biology has been obtained, and has led in one direction to the successful trial of systemic insecticides for the control of the disease, and, in another, to the study of the possibilities of a new and important means of biological control based on the provision of alternate hosts for the predators of the vector. The demonstration that dry-season volunteer groundnuts can carry rosette disease and its vector over into the new season has been followed by the discovery that certain long-season varieties exhibit marked seed dormancy, which delays the appearance of volunteers for many months and so automatically provides a close season to prevent the carry-over of the disease. More recent work suggests that some of these long-season types are, in addition, resistant to some forms at least of rosette disease.

Scarcely less important has been the demonstration that benzene hexachloride, placed near the seed at planting time at the rate of about 4 oz. gamma-isomer per acre, can control the attack of termites on the standing crops as they approach maturity several months later. The biological staff have also given major help in such matters as seed selection, storage of agricultural products and the control of termites in buildings.

The attention of the Department has been so largely concentrated on field work that the laboratory side has seemed to occupy a second place. For a long time there were no laboratory facilities at all, yet valuable studies were carried out using portable or improvised equipment. For two years the headquarters laboratories were housed in tents; but on August 20, 1951, the Kongwa chemical laboratory, a well-equipped establishment of modern design, was formally opened after having been in use with temporary fittings for eighteen months. The remaining laboratories at Kongwa have been housed in converted accommodation for the same period. At all times, however, the Department has had a reliable routine laboratory service. The chemical staff have analysed many thousands of soils and of crop samples, and their work has also extended to the analysis of fertilizers, studies of the effect of shipment and storage on produce, work on the contamination of crops and analyses arising from pedological problems. Much help has been given to other departments of the Corporation, and the Scientific Department was responsible for the chemical aspects of the recent experiments at Kongwa on the artificial precipitation of rainfall.

The statistical section has been responsible for the design and analysis of more than seven hundred field experiments of modern design, ranging in size from 16 to 300 plots, and has had considerable responsibilities in the planning of programmes and in the evaluation and reporting of results. In addition to papers which have appeared in the specialist and technical Press, the Department has issued annual reports for 1947–48, 1948–49 and 1949–50, which have been summarized in the annual reports of the Corporation published by H.M. Stationery Office. The full data on which these reports have been based may be obtained in mimeographed form from the Scientific Department, Overseas Food Corporation, Kongwa, Tanganyika.

EIGHTH INTERNATIONAL CONGRESS OF REFRIGERATION

THE Institut International du Froid (I.I.F.), which has its headquarters in Paris, normally arranges for an international congress to be held every four years in one of its member countries. The intervention of the war years, however, broke the continuity of its meetings and no congress had been possible since that held in the Hague in 1936. For this reason the recent Congress, held at Church House, Westminster, during August 28–September 10, had more than usual significance, and the field of activity to be reviewed was particularly wide.

The presidency of the Congress was shared by the Right Hon. Viscount Bruce, of Melbourne, and Prof. W. J. De Haas, of Leyden. The Institute of Refrigeration in Great Britain undertook the arrangement of all meetings and functions. The attendance was approximately seven hundred, of which the proportion of overseas visitors was more than two to one. Thirty countries were represented.

The work of the Congress was divided among seven commissions, the subjects of which ranged from low-temperature physics and the low-temperature industry through all branches of refrigeration, including purely biological problems associated with the storage of food and other perishable materials, to problems of statistics and education in refrigeration.

In the meetings of Commission I, no attempt was made to embrace the general field of low-temperature physics, since by agreement this was delegated to the Oxford Low Temperature Conference held a few days previously (p. 807). One session was devoted to the subject of hydrogen and helium liquefaction. This meeting directed attention to the present situation, where there are now scores of laboratories throughout the world equipped to produce liquid hydrogen or helium. In the case of helium liquefaction, while many laboratories use the Simon direct-expansion type of liquefier, a description was given of a small completely automatic helium liquefier, employing a Collins expansion engine, which is now produced commercially in the United States. Dr. A. Wexler, of the Westinghouse Research Laboratories, Pittsburgh, also described a type of small metal Dewar vessel for liquid helium which has an evaporation loss of only one per cent per day. The vessels are shielded by liquid nitrogen boiling under atmospheric pressure. He suggested that larger vessels for storing liquid helium for as long as a year could readily be constructed.

A further session, devoted to thermodynamics, heard reports on the construction of thermodynamic charts for pure substances both by the Kamerlingh Onnes Laboratory, Leyden, and by the Heat Division of the Mechanical Engineering Research Organization (Department of Scientific and Industrial Research). So far, at Leyden, eleven diagrams have been completed and made available for the common industrial gases and helium; while the British body has also completed preliminary surveys for air, carbon dioxide, acetylene, propane and ammonia.

A paper by Prof. Jiro Oishi, of Japan, described a new experimental procedure for determining the absolute temperature of the ice point by the isotherm method. Two advantages were claimed: first, the elimination of dead-space errors, and, secondly, greater reliability of the results since the measurements can be confirmed by the use of at least six different gases in the thermometer. The mean value of the ice point determined by these experiments is 273·15, compared to the mean value of 273·155 obtained from the experimental results of all workers since 1929. Considering both sets of data and the absolute accuracy of the method, he proposed 273·15 to be the best value now available.

Measurements of heat transfer were reported by many authors both to Commissions I and II, the range of temperatures extending from normal refrigeration temperatures down to that of liquid hydrogen. New values for the thermal conductivity of liquid nitrogen were given by Prof. H. L. Johnstone, Ohio State University, while Prof. L. Weil, of Grenoble, gave values for the rate of heat transfer to boiling liquid hydrogen.

The greatly increased importance and activity of the low-temperature industry both in Great Britain and abroad was evidenced by the fact that no fewer than twelve papers were given on subjects connected with industrial gas separation and liquefaction. Many of these were concerned with plant for separating air into its constituents, from the scale of small transportable units mounted on trailers to single industrial units for producing 1,000 tons of oxygen a day. The increasing use of argon-arc welding for fabricating aluminium and alloy steels focused attention on methods of extracting this gas from the atmosphere. The separation of ethylene from coke oven gas and from the gases obtained by the cracking of oil is another field in which low-temperature gas separation is now widely practised.

A further contribution to this session was an account of the work pioneered by Sir Alfred Egerton at the Imperial College of Science and Technology, London, into the utilization of liquid methane. Trials with motor vehicles adapted for running on liquid methane, carried in a vacuum-jacketed tank, have now totalled about 25,000 miles, of which the greater part has been made with buses in full passenger service. It is considered that sufficient knowledge now exists for the use of liquid methane as an automotive fuel to be considered for certain types of vehicles where methane is available. The use of stored liquid methane to meet peak loads at gas works was also discussed.

Commission III of the Congress was concerned with fundamental biochemical and biophysical studies related to refrigeration. Dr. P. Becquerel reported on experiments in which dehydrated organisms such as Protozoa, seeds, and spores of bacteria and fungi were mixed with iron alum powder and cooled by the magnetic method to within 0·2° C. of absolute zero. All the organisms frozen in this way recovered their full vital activity when thawed. It is thus shown that by the action of dehydration, vacuum, and extremely low temperatures it is possible to suppress the colloidal state of protoplasm necessary for biological changes without affecting its power to recover.

In organisms having a higher water content, the chance of survival decreases, although it was shown by Dr. L. Geneves in experiments in which microscope observations were made of cooling thin sections from the roots of the chicory plant that the disturbance of the cell structure by cooling was often reversible on thawing. Similar work was reported by Miss I. Modlibowska, East Malling Research Station, who directed attention to the causes of frost injury to fruit trees, relating it to the water content of the affected cells. The effect of low temperatures on the survival of animal cells was discussed by Dr. L. Bucciante. The usefulness of these researches was instanced by the present use of the low-temperature preservation of animal spermatozoa and of insulin in frozen pancreatic glands.

A novel approach to these problems described by Dr. W. H. Cook, National Research Council of Canada, involves the study of freezing processes in artificial cells constructed from 'Cellophane' or rubber. Films produced from these materials exhibit high resistance to penetration by ice crystals.

The effect of low temperatures on enzyme activity was discussed by Prof. M. A. Joslyn (California) and others. While this field is still only partially explored, it appears that the concentration of the substrate by freezing of some of the water may protect the enzyme and allow the continuance of its activity at lower temperatures than would otherwise be possible.

A further biological problem which arises in refrigerated food storage is the shrinkage and loss of weight of meat and fish which can occur on thawing, due to the extrusion of fluids from muscle. In this field a most valuable paper was presented by J. R. Bendall (Department of Scientific and Industrial Research) and Dr. B. B. Marsh, of New Zealand. They have been able to relate the shortening of muscle fibres and the consequent extrusion of liquid to the decline in the concentration of adenosine triphosphate in the muscle. The reversibility of the process has been demonstrated, and also its dependence on the pH value.

The present state of gas storage for apple and pears was outlined by Dr. C. West, of the Low Temperature Research Station, Cambridge. Wide experience has now been gained in the optimum refrigeration temperature and composition of atmosphere required for different varieties, and the importance of this method is such that it already provides storage for 80,000 tons of fruit in Great Britain alone. Other speakers reported its use overseas.

The work of other commissions covered the purely technical and engineering questions involved in the design of refrigerating machines and insulated chambers of all types. Facilities were also provided for members of the Congress to visit research laboratories and industrial installations in many parts of England and Scotland.

The occasion of the Congress was made the opportunity for drawing up and sanctioning extensive measures for the reorganization of the International Institute of Refrigeration under its new director, M. C. David. It is a matter of the greatest satisfaction to scientific men and refrigeration engineers in Great Britain that Dr. Ezer Griffiths was elected as the new president of the General Conference of the International Institute of Refrigeration; he is succeeded in his post as head of the Technical Board of the Institute by Prof. C. J. Gorter, of the University of Leyden.

G. G. Haselden

LOW-TEMPERATURE PHYSICS

THE conference on low-temperature physics, held at Oxford during August 22–28, constituted the second meeting of the Commission for Very Low Temperatures of the Union de Physique Pure et Appliquée, the first having been held at the Massachusetts Institute of Technology in 1949; and at the same time it formed part of the first post-war meeting of the Institut International du Froid, which has a Commission primarily interested in the pure physics of low temperatures. A conference on the technical and industrial aspects was held in London (p. 806) immediately after that at Oxford. Visitors were invited to the Royal Society Mond Laboratory at Cambridge on August 21.

A feature of the Oxford conference was the presence of a large number of younger research workers who, the organizing committee felt, had in general insufficient opportunities of attending international meetings of this kind. They were able to be there through the generosity of the Royal Society and a number of industrial organizations, the contributions of which substantially augmented the grant made by the Union de Physique from Unesco funds. The presence of a large number of delegates from the United States was ensured through the continued support of the Office of Naval Research.

Except for three introductory papers, contributions were limited in duration to ten, fifteen or twenty minutes. The total number was about a hundred and ten. A reporting system similar to that of the Harwell conference on nuclear physics (1950) was used, with the aid of fifty of the junior research workers, to make the report available in a few weeks.

In the following account, papers are grouped under the same four headings as at the conference.

Thermal Properties

A noticeable feature of this section was the general attempt to measure quantities such as specific heat, thermal conductivity and electrical conductivity over a continuous temperature range, where previously considerable gaps had existed. A number of workers have pushed these measurements below 1° K., and some private discussion took place on the temperature scale in this region. Discrepancies still exist between different laboratories even above 0·2° K.; below this temperature the discrepancies become considerable, but, until the problem of heat transfer to and from the paramagnetic salts used as cooling agent is solved, this does not seriously affect work except on the properties of the salts themselves.

Work on the specific heat anomaly in solid deuterium was reported by H. L. Johnston, and in solid hydrogen by R. W. Hill. It seems probable that the origin of the anomaly is splitting of the rotational degeneracy by the crystal field. Hill also reported that pure germanium shows no anomaly, and E. Estermann showed that the anomaly previously found is connected with the presence of impurity. Measurements on neptunium and thorium oxides (NpO_2 and ThO_2) (E. F. Westrum) showed that the anomaly in the former is magnetic in origin, like that of uranium oxide (UO_2).

Work on solid helium at high temperatures was concerned with the possibility of a critical point in the solid–fluid equilibrium. J. S. Dugdale reported that entropy measurements give no indication of approach to such a point, and that two phases have been found in the solid state, with a latent heat of transition. F. E. Simon suggested that these represent close-packed hexagonal and cubic states. The melting curve below 4° K. has been further investigated by C. A. Swenson. The melting curve of the light isotope, helium-3 (B. M. Abraham), has been measured between 1·5 and 0·16° K. Above 0·5° K. the melting pressure is $p = 26·8 + 13·1\ T^2$ atmospheres, while below it approaches a constant value of 29·3 atmospheres; this may be due to a transition in the liquid, or to the experimental difficulty of lack of heat contact with the paramagnetic cooling salt.

R. Berman reported that work on the thermal conductivity of dielectrics gives general confirmation of theory. The maximum in the thermal conductivity occurs at about a twentieth of the Debye temperature and amounts to 60 watts/cm. for sapphire. Work on solid helium (J. Wilks) is of interest because of its large change of density under pressure. The low thermal resistance of some crystals raises the possibility of observing 'second' sound in them. Work on the thermal conductivity of metals at Oxford and Ohio State University is concerned with the question of the minimum which, according to E. H. Sondheimer, is a rigorous consequence of the Bloch–Nordheim theory.

A considerable amount of work was reported on the electrical resistance of both pure metals and alloys, partly directed towards the discovery of suitable secondary thermometers and partly for comparison with theory. Hitherto, it has been generally accepted that the resistance reaches a constant value at low temperatures, but a number of metals show a minimum of resistance. E. Mendoza has investigated specimens of silver, gold and copper below 1° K. and finds a sharp increase in the resistance at the lowest temperatures. There seems to be no explanation for this at present.

Liquid Helium

In an introductory lecture, F. London surveyed the present position in the theory of liquid helium. Further work has revealed some of the limitations of the two-fluid model, though there is no doubt that this is basically correct. These limitations are connected with the existence of a limiting velocity in the rate of transfer, and the presence of dissipative forces at high rates of transfer. A more fundamental difficulty is the lack of a satisfactory molecular theory, although considerable progress has been made in the molecular theory of ordinary liquids. The fact that the light isotope, helium-3, shows no superfluid characteristics down to 0·25° K. suggests that the nature of the statistics, Bose–Einstein or Fermi–Dirac, must play an important part.

Measurements on liquid helium at Cambridge were reviewed by K. R. Atkins. Below 1·6° K. the velocity of 'first' sound approaches asymptotically the value 237 ± 2 m./sec., while previously the velocity of 'second' sound has been found to tend towards 152 ± 5 m./sec. at 0·2° K. The ratio of these velocities departs slightly from the simple Landau theory value of $\sqrt{3}$, but this may be due to dispersion.

Experiments on the flow of liquid helium II were mainly concerned with evaluating the nature of the frictional forces. The theory of Gorter and Mellink postulates a frictional force proportional to the cube of the difference of the velocities of the normal and superfluid. Measurements at Leyden, described by P. Winkel, have been designed to determine the proportionality constant and its variation with temperature; it seems possible that some interaction between the superfluid and the walls may have been present. Such an effect is suggested also by experiments of B. S. Chandrasekhar and K. Mendelssohn. Work at Cambridge, including a modified form of the Andronikashvili experiment, suggests that frictional terms involving only the velocities of the individual components may be present. R. Bowers discussed experiments in which the pressure at an intermediate point in the flow was measured, which indicated that frictional terms may only be required to explain flow above a certain critical rate.

Measurements down to 0·25° K. on the specific heat of liquid helium were described by H. C. Kramers. Above 0·7° K. the specific heat diminishes with a power of the temperature between 6 and 7, in agreement with previous work, but then changes rather abruptly to follow a third-power law at lower temperatures, with an absolute magnitude not in serious disagreement with that predicted by the theory of Landau.

A number of papers were presented on measurements of dilute solutions of helium-3 in helium-4. J. G. Daunt and C. V. Heer showed that a quasi-gaseous model of a Bose–Einstein liquid can be used to explain the properties of such solutions, without assuming that helium-3 dissolves only in the normal component of the fluid, as has been suggested by K. W. Taconis.

An interesting experiment of a novel kind was discussed by J. R. Pellam. He showed that a Rayleigh disk can be used for investigating 'second' sound; the use of a disk permeable only to the superfluid will give results on the densities of the normal and superfluid components, the entropy and the specific heat.

Papers on theoretical aspects ranged from the viscosity of gaseous helium-3 and helium-4 (J. H. de Boer) to the hydrodynamics of superfluids (I. Prigogine); the resurgence of physics in Japan was emphasized by a number of papers, read by M. Kotani.

Superconductivity

The session opened with a review by H. Frohlich of his new theory of superconductivity. The problem of finding an interaction mechanism leading to a new electronic state different from the usual state by a small enough energy has been solved, but it has not yet been possible to show that this will lead to superconductivity. The interaction is between the electrons and lattice vibrations through spontaneous emission and absorption. This differs from that in electromagnetic theory in that the velocity of the particles (electrons) is much greater than that of the waves (phonons). The interaction depends on the ionic mass, and so gives rise to the isotope effect; on the simple theory the transition temperature should vary with the inverse one-half power of the isotopic mass. A new fundamental length of the order of 10^{-6} cm. appears, which may be connected with long-range order effects. M. R. Schafroth described an attempt to show that the theory leads to the London equations, but A. B. Pippard suggested that the true equations might be integral equations with the Meissner effect not implicit but imposed as a condition of the solution. On the experimental side, Pippard pointed out that the sharpness of the transition temperature with a mixture of isotopes implies that groups of at least two thousand atoms be involved simultaneously to avoid a spread due to random variations in the isotopic distribution, while groups of 10^{10} atoms are required to avoid a spread due to temperature fluctuations. This, and the smallness of variations in the penetration depth with magnetic field at constant temperature, suggest that the interactions have a range of the order of 10^{-4} cm. This range might be affected by impurities.

Experimental work on the isotope effect was reported by E. Maxwell, who finds that in tin the transition temperature varies with the power $(-0{\cdot}486 \pm 0{\cdot}031)$ of the isotopic mass, while in lead the power is $-0{\cdot}73$ (Mrs. M. Olsen-Baer). A striking result in work on thin films by R. Hilsch is that bismuth condensed from the vapour at 4·2° K. is superconducting, but, after annealing at room temperature, it is not. Among many other papers on superconductivity, mention should be made of a superconducting galvanometer (F. T. Pullan), with a voltage sensitivity of 10^{-12} volt. It is being used to measure the thermoelectric e.m.f. around a tin–lead circuit the junctions of which differ in temperature by only 0·01°. Experimental and theoretical work on the de Haas–van Alphen effect was reported from Cambridge.

Magnetism

In a review of recent advances in paramagnetism, B. Bleaney showed how the use of paramagnetic resonance has made possible the investigation of the behaviour of the ionic energy levels in a magnetic field in a detail which could not be achieved by previous methods. This is particularly valuable in the study of hyperfine structure, since in dilute salts the position of levels as close as 0 001° K. can be determined. This has made possible the analysis of the degree of nuclear alignment by methods such as have been suggested by Gorter and Rose. The information obtained has given impetus to new theoretical work: in the iron group, by Abraham and Pryce, and in the rare earths, by Elliott and Stevens. In the latter case, the use of a crystalline electric field of axial rather than cubic symmetry accords well with the experimental results on the ethyl sulphates. A. H. Cooke described the paramagnetic properties of cerium ethylsulphate, the high anisotropy and low susceptibility of which normal to the crystal axis suggest its use for measurements below 1° K. A magnetic field could then be applied normal to the axis without producing appreciable heating of the salt.

A concentrated attack on the antiferromagnetic state below 4·5° K. in copper chloride was reported from Leyden, measurements having been made on the susceptibility, the paramagnetic resonance spectrum and the nuclear resonance spectrum in a single crystal. The behaviour of the magnetization is in accordance with the theory of Néel, and the effective moment of the cupric ion can be calculated from the nuclear resonance spectrum.

Further measurements on remanence, hysteresis and similar effects in paramagnetic salts at temperatures of the order of 0·01° K. were described by D. de Klerk and M. J. Steenland. It seems that the behaviour observed resembles that of more concentrated salts at higher temperature, being antiferromagnetic in nature. Lack of dependence on the Curie point on shape suggests that it is due to exchange forces rather than magnetic dipole–dipole forces.

After a review of possible experiments with oriented nuclei by M. H. L. Pryce, C. J. Gorter gave a short account of work at Leyden. This has included experiments with gamma-ray emission and the absorption of unpolarized neutrons; one somewhat doubtful positive result has been obtained, the rest being negative. J. M. Daniels reported on work in progress at Oxford.

Two-stage demagnetization experiments using a superconducting wire as a heat-switch were described by J. Hatton. With a starting field of only 9 kilogauss, a temperature of 0·0011° K. has been reached, and the sample remained below 0·01° K. for forty minutes. B. V. Rollin showed that nuclear resonance experiments on a natural crystal of beryl have confirmed the value of 3/2 for the nuclear spin of beryllium-9 from observation of the quadrupole splitting, and a previously unobserved line has been ascribed to silicon-29, with a gyromagnetic ratio of 1·11.

R. Bowers

OBITUARY

Prof. F. W. Oliver, F.R.S.

Francis Wall Oliver was born on May 10, 1864, at Richmond, Surrey. On the paternal side he came of a Northumbrian Quaker stock; his great-grandfather, Daniel Oliver (1771–1848), was well known as a preacher among Friends in the North of England. Though F. W. Oliver did not remain a member of the Society, certain traits in his character, such as his unyielding individualism, may perhaps be associated with his Quaker origin. His father—the third Oliver in direct succession to bear the name of Daniel—was keeper of the Herbarium at Kew during 1858–90, and, concurrently, professor of botany at University College, London, during 1860–88. His official house on Kew Green, where F. W. Oliver was brought up, had been occupied previously by Sir Joseph Hooker. Frank's childhood memories included meetings with botanists whom few now living can recall, such as M. J. Berkeley (1803–89) and Asa Gray (1810–88). In 1871, when he was seven years old, George Bentham (1800–84) gave him the book by Edward Lear which contains the "Nonsense Botany", with its deliciously absurd pictures, closely resembling those in certain medieval manuscript herbals.

Frank Oliver was sent to Friends' schools at Kendal and York, and then, after a period at University College, London, to Trinity College, Cambridge. In those days the best training in research was to be had in Germany, and in 1885 and 1886 his initiation took place under Strasburger and under Pfeffer. Daniel Oliver retired from the professorship at University College in 1888, and F. W. Oliver, though only twenty-four, succeeded him as head of the Department. In this capacity he revealed a breadth of sympathy, which enabled him to draw out the individuality of his pupils, while he also had so wide a range of knowledge that it was possible for him to meet and help each student, wherever his chosen ground might lie. The catholicity of his interest would be difficult to parallel in these days of specialization. He once described how he had, in youth, worked through a whole century of the botanical volumes of the *Annales des sciences naturelles*, adding, as a final comment—"and great fun it was". In his personality, however, it was not the purely intellectual aspect of things that was in the ascendant. His physical hardihood, and the determined keenness of his face —he characterized a certain silhouette of himself as "the old hawk"—marked him as a man in whom thought was the handmaid to action. Among his students half a century ago, it was said that F. W. Oliver was born to be a naval officer rather than a professor. There was a prophetic touch in this dictum, in view of the subsequent naval careers of his two sons—Vice-Admiral Sir Geoffrey Oliver, commander-in-chief, East Indies Station, and Captain (E) P. D. Oliver, R.N. Their father's love for an adventurous outdoor life was fostered in childhood by a glorious year of running wild in Jersey, where his grandparents lived. Later on, it found its outlet in mountaineering. This passion dated from his school days in Westmorland; it was shared by his wife, whom he first met when they were both waiting at Zermatt to climb the Matterhorn. The mountain fervour eventually had to give way to an absorbed pre-occupation with coastal regions, the ecology of which came to play a leading part in his departmental programme.

In the latter part of the nineteenth century, university botany had become predominantly an affair of the laboratory and botanic garden, and there was little organized field-work for students. Oliver once wrote that, in the eighteen-eighties, the 'country' was regarded primarily as a source of 'material' for the stocking of laboratory shelves. It was not, indeed, until early in the present century, when ecology had begun to breathe fresh life into outdoor botany, that an attempt was made from University College to carry out a systematized survey of the vegetation of an individual locality. The pioneer effort took the form of an expedition to the Norfolk Broads in 1903. After this tentative experience, Oliver chose the Bouche d'Erquy, on the north coast of Brittany, twenty-five miles west of St. Malo, as an ecological centre for his Department; the visits paid to it covered the period 1904–9. The primary object of the first year's work was to map and level the physical features and plant-associations, as a basis for further research. In later years a variety of experimental and ecological techniques was employed (*New Phyt.*, 3, 1904, and later years). A. G. (now Sir Arthur) Tansley, who has since been so largely responsible for the development of ecology in Great Britain, had much to do with the initiation of the Erquy studies. Another ecologist, closely associated with Oliver's vegetation surveys, was E. J. (now Sir Edward) Salisbury, who eventually succeeded him in his professorship. From 1910 onwards, Oliver's ecological activities were transferred to Blakeney Point in Norfolk—an area which has since come under the control of the National Trust (*Trans. Norfolk and Norwich Nat. Soc.*, 9, 1909–14, and later years). Many of the Blakeney observations find a place in Tansley's work, "The British Islands and their Vegetation" (1939; ed. 2, 1949).

It was not in Oliver's nature to confine himself to the ivory tower of academic botany; he was constantly trying to apply his ecological experience to the needs of man. Evidence of this will be found in two team-work books which he edited—"The Exploitation of Plants" (1917) and "Life and its Maintenance" (1919). Both of these were based on public lectures at University College, dealing with problems the urgency of which emphasized itself during the First World War. Oliver's contribution to the first volume was on the reclamation of waste lands, while, in the second volume, he discussed the use of certain grasses as substitute raw material for paper. In another book, "Tidal Lands" (1918), he collaborated with A. E. Carey, a maritime engineer, in a study of the maintenance of coastal and riparian areas. In this work he describes the part played by plants in fixing dunes, and in reclaiming shingle beaches and salt marshes. He lays special stress upon *Spartina Townsendii*, the grass that he called "a Gift from Heaven", on account of its mysterious origin, and its almost miraculous power of transforming salt marsh mud into land suitable for reclamation. In the autumn of 1950, at the age of eighty-six, he re-visited the Dutch *Spartina* fields, to study the progress they had made since the first batch of cuttings was sent to Holland more than twenty-five years before.

The special courses of lectures, often by outside men of science, which were a feature of F. W. Oliver's Department, and to which I have alluded in connexion with the economic aspect of his work, also gave the opportunity for dealing with other topics not included in examination syllabuses, such as the history of botany. Oliver had inherited and extended his father's collection of old herbals and of the work of botanical draughtsmen, and his interest in the subject found expression in organizing courses on the historical aspect of plant delineation, and of botanical study in Great Britain. Some of these lectures were incorporated in a book which he edited, "Makers of British Botany" (1913).

F. W. Oliver's own personal research had its focal centre in palæobotany. His friend, D. H. Scott, inspired him with fervour for the subject, and his early enthusiasm was closely linked with a course of lectures which Scott gave at University College in 1896, and which were afterwards published as "Studies in Fossil Botany". Oliver specialized in the complex seeds of Carboniferous plants, and examined modern gymnosperms, such as *Torreya*, to find material in which to trace the phylogenetic history of seed structures. Coal Measure seeds are commonly seen only in detachment from the parent plant, so that, in the early days of these studies, their attribution was conjectural. In looking through the Williamson Collection of sections of Carboniferous plants at the British Museum in 1902, Oliver noticed certain anatomical features which practically proved that the fossil seed, known as *Lagenostoma lomaxi*, belonged to the fern-like plant, *Lyginodendron oldhamium* (now called *Lyginopteris*). He reported what he had seen to Dr. Scott, and asked him to collaborate in an account of this identification. Such a suggestion was natural, since the Williamson Collection was, in a moral sense, Scott's property; in order that it might belong to the nation, he had bought it when the opportunity arose, the British Museum repaying the debt by instalments. Scott, however, held very decidedly that the epoch-making *Lagenostoma* discovery should be published by Oliver independently; but Oliver remained determined that it should be joint work, and he finally prevailed upon Scott to agree. The collaboration was complete; Oliver has assessed their contributions as being "50/50 both in the descriptive and theoretical parts". In their memoir, "On the Structure of the Palæozoic Seed *Lagenostoma Lomaxi*, with a Statement of the Evidence upon which it is referred to *Lyginodendron*" (*Phil. Trans. Roy. Soc.*, Ser. B, 197, 193; 1904), the name Pteridospermeæ was proposed for fern-like plants bearing seeds; Oliver and his pupils afterwards investigated other members of the group. Scott always accorded the fullest recognition to Oliver's primary part in unravelling the *Lagenostoma* secret; this became strikingly evident when the Pteridosperm nature of *Lyginopteris* was clinched, once and for all, at the Cambridge meeting of the International Botanical Congress in 1930. At this meeting well-preserved impressions of *Sphenopteris hœnighausi* (the foliage of *Lyginopteris oldhamia*) actually bearing cupules and seeds were exhibited by W. J. Jongmans. At the end of the paper, Scott, who was presiding, left the chair, and disappeared quietly from the room, thus compelling Oliver "to take the 'curtain' alone". (See notices of D. H. Scott by A. C. Seward in "Obit. Not. Fellows Roy. Soc.", 205; 1934, and by F. W. Oliver, *Ann. Bot.*, 49, 823; 1935.) In 1905, the year following the appearance of the *Lagenostoma* paper, Oliver was elected to the Royal Society, and in 1925 the Linnean Medal was awarded to him.

The year 1929 was a turning point in Oliver's career. His marriage in 1896 to Mildred Alice Thompson had given him a home atmosphere of rare and delightful quality, in which all his activities could expand and flourish. The only shadow was the distressing illness of their third child, Faith, who was partially paralysed, and for twenty years required ceaseless care, which Mrs. Oliver gave with unstinted devotion. This invalid daughter died in 1929, and her parents were then free to embark on an entirely different mode of life. Later in that year, Oliver, being then sixty-five, retired from University College, though pressed to continue for a further period. 'Fougasse' marked the occasion by an admirable cartoon, depicting F. W. Oliver soaring into the air, pipe in mouth, from the top of the portico steps of the College, his discarded cap and gown in flight behind him. The drawing was inscribed: "The Boy—What will he become?"—a query which was answered by his appointment in the same year to the professorship of botany in the Fouad I University, Cairo, a post which he held for five years. For the first three winters, Mrs. Oliver was able to be with him at Heliopolis; a vivid picture of their cosmopolitan life there is given in her "Letters from Egypt", printed after her death in 1932.

Even after Oliver had retired from this second professorship, he remained in Egypt, which became more exclusively his home than he had anticipated, since the War put a stop to his annual visits to England. For fifteen years he lived in a house he had built at Burg-el-'Arab in the Western Desert, thirty miles west of Alexandria. There was no irksomeness for him in the remoteness and isolation of his chosen spot; ennui was not within his experience. Many years ago, when he lay ill in a nursing home in the dreary precincts of Fitzroy Square, he replied to a visitor, who had ventured to condole with him on the tedium of this imprisonment: "*Nothing* is boring". Indeed, in Egypt, under the stimulating influence of surroundings not staled by custom, his interests took on a renewed lease of life. One of his special concerns, European coastal problems, suggested lines of approach to certain urgent Egyptian questions. In 1941 he published, under the auspices of the Egyptian Ministry of Agriculture, a paper on "The Sand-Dune Menace", in which he urged long-term planning for the stabilization of wandering dunes. In other articles he dealt with desert duststorms (*Geog. J.*, 106, 26; 1945; 108, 221; 1946). He continued, as ever, to view all manifestations of life with the eye of an artist-naturalist, whether he was describing lyrically the "chromatic symphony" of the Maryut flowers, or with equal pleasure observing a garden plant of *Agave americana*, with a flowering shoot more than 27 ft. high, raining nectar in a wind from its myriad perianth cups, each the size of a small liqueur glass. Again, as occasion served, he recorded the ways of ants, hornets, snails, sparrows, or the larvæ of a psychid moth; or he assembled, for packing material, the resilient balls of *Posidonia* fibres, which the sea cast up in their hundreds; or he collected on his rambles, with discriminating zest, handles of amphoræ, believed to have been imported from the Greek islands in Ptolemaic times, some "still carrying their impressed trade-marks—fresh and bright as the day they left the kiln".

In 1950, after twenty-one years in Egypt, Oliver concluded negotiations for the transfer of his property to the Farouk I University, Alexandria, for use as a field station. He then returned to England, and reinstated himself in his former home, Ballard's Barn, Limpsfield Common. Here the end came with complete suddenness on September 14, 1951.

Throughout his life, Oliver never ceased to observe and to record. Less than a month before he died he sent to me specimens and notes relating to a mutant form of *Salvia horminum*, which had appeared this summer in his garden. To the last he defied time, and looked forward to the enjoyment of yet more flowering seasons; in his eighty-eighth year he declared his intention of planting "3 Magnolias together in an appropriate border".

AGNES ARBER

NEWS and VIEWS

Forestry in the University of Edinburgh : Prof. M. L. Anderson

Dr. M. L. Anderson has been appointed to the chair of forestry in the University of Edinburgh recently vacated by Prof. E. P. Stebbing. Dr. Anderson, who already holds a doctorate of the University, brings to his new post a wide experience of British forestry, having served first in the Forestry Commission, both as a district officer and as a research officer, and then in Eire, where he was director of forestry for the period 1940–46 and had to deal with the practical and administrative problems connected with the severe war-time shortage of timber and fuel. In December 1946 he joined the Imperial Forestry Institute at Oxford, where he was responsible for instruction and research in forestry mensuration and British forestry practice. Dr. Anderson has a wide reputation as a sylviculturist with special knowledge of the native hardwoods of Britain, particularly the oaks, to which he has devoted a great deal of out-door and literary research ; his most recent publication is a very detailed study of the status of the sessile oak in the New Forest, and his alleged partiality for this species has long been the subject of friendly chaff. Another pronounced preference shown in his work and writings is for an uneven-aged structure of woods and group regeneration, and he has done much to collect experimental data bearing on the matter. His recent publication on the choice of species in relation to site factors is an important contribution to the literature of the subject and reveals a wide knowledge of this leading aspect of the vast afforestation task in Great Britain. His translation of Tamm's work on "Northern Coniferous Forest Soils" illustrates another task he has frequently undertaken, that of making available to the English-speaking forester the published material and views of leading foreign workers on subjects of importance to Great Britain. Dr. Anderson is one of the few British foresters for whom Swedish, and even Russian, present no serious difficulty. As a contribution towards the investigation of another of the major current forestry problems in Britain, during his time at Oxford Dr. Anderson undertook a study of the relation between the State and private forestry in the Western democracies. Dr. Anderson's appointment at Edinburgh is a very appropriate recognition of the large share he has taken in the advancement of knowledge and thought in the field of forestry, and the effects on the coming generation of his teaching and his example in his new post are likely to be far-reaching.

Education in the University of Edinburgh : Sir Godfrey Thomson

Sir Godfrey Thomson, who retired this year from the chair of education in the University of Edinburgh and from the directorship of Moray House Training College, has made a distinctive contribution to the theory and practice of mental testing. On the theoretical side, he has been a critic of the bold generalizations of Spearman and others, and his work on sampling and the influence of selection upon the factors in a correlational matrix stresses the need for caution in this field. On the practical side, Sir Godfrey has made Moray House the major British centre for the provision of intelligence tests in schools. He has also been concerned with population trends and a possible decline in our national intelligence. His Galton Lecture in 1946 dealt with this topic. He was chairman of the committee which carried out the Scottish Mental Survey of 1947, and is continuing his researches on the data which that survey provided. Sir Godfrey has also achieved notable success as a teacher, and the contribution made to educational and psychological research by his pupils is very great. There are at present no less than ten professors of education or psychology who have studied under him.

Prof. J. G. Pilley

Prof. John G. Pilley, who succeeds Sir Godfrey Thomson, is a Londoner who graduated in natural science in the University of Oxford in 1922. After three years as a research physicist, he became a university lecturer in education at Liverpool for a year and then, from 1926, at Bristol. In 1937 he went to the United States by invitation of the Rockefeller Trustees and Columbia University to study the teaching in American schools and to help in formulating proposals for the reform of the teaching of science. On the outbreak of the Second World War he was prevailed upon to take charge of the Department of Education at Wellesley College, Massachusetts, the post he now relinquishes. Though a man of science, and a successful teacher of science, it is in the philosophy of education that Prof. Pilley's interest is centred. He stands by the values embodied in the educational tradition of classical liberalism against every form of facile modernism. He has made his mark in America as a vigorous critic of the tendency to make education 'scientific', holding that this means, in effect, to anchor it to values that are shiftingly pragmatic, and often ephemeral. His published writings, though slight as yet and mostly topical, have a quality and direction which suggest that he has an important contribution to make to educational theory ; perhaps, in particular, to the solution of that most urgent contemporary problem, the effective integration of science in the theory and practice of a liberal education.

F. M. Balfour (1851–82)

Born in Edinburgh a century ago, on November 10, 1851, Francis Maitland Balfour, a younger brother of the statesman Arthur James Balfour, was one of the most distinguished of British zoologists and embryologists of his time. At the age of twenty-two he did original work at Cambridge on obscure points in the development of the chick, and at the Zoological Station in Naples, under Anton Dohrn, he elucidated the embryonic history of the Elasmobranchs, which was then little understood. This latter research, published in the *Quarterly Journal of Microscopical Science* (1873–75), won him a fellowship of Trinity College, Cambridge, and a lectureship on animal morphology in the University. His classical "Treatise on Comparative Embryology" (two vols., 1880–81), a masterly digest of the previous knowledge on the subject and embodying his own original contributions, was instantly recognized by his fellow scientific workers. In the graphic words of his teacher, Michael Foster, it "brushed away many cobwebs and mooted points with a firm but courteous sweep", and it laid the foundation of the modern study of descriptive embryology. Balfour's numerous honours included the fellowship of the Royal Society in 1878, one of the Society's Royal Medals three years later, and the professorship of animal morphology in the University of Cambridge, which was created for him in 1882. For several years he was one of the editors of the *Quarterly Journal of Microscopical Science*. In the summer of 1882 Balfour went to Switzerland to recuperate from an attack of typhoid fever. He and his guide were killed, probably on July 19, while attempting to climb a virgin peak on Mont Blanc. His tragic death at the early age of thirty-one robbed the world of science of one of its most imaginative, original, attractive and promising workers.

Institute of Navigation : Medal Awards for 1951

The Gold Medal for 1950–51 of the Institute of Navigation has been awarded to H. C. Pritchard for valuable contributions to navigation made over a number of years in the field of airborne navigation equipment. In 1939 Mr. Pritchard formed the Navigation Section at the Royal Aircraft Establishment, and it was in a large measure due to his personal guidance that practical solutions were found to many of the air navigator's problems. Mr. Pritchard's team successfully developed the distant-reading and gyro-magnetic compasses, the air mileage unit, air position and ground position indicators, the drift recorder, the astrograph and the astro-compass. Later during the War, Mr. Pritchard was given responsibility for the formation of an experimental unit to deal with problems of blind approach and landing, and important advances were made in the art of all-weather flying.

Bronze Medals, for the best paper to be published in any year in the Institute's *Journal*, have been awarded to R. F. Hansford (development of ship-borne navigational radar), C. S. Durst and N. E. Davis (jet streams and their importance to air navigation), and Captain F. J. Wylie, R.N. (ret.) (radar and the rule of the road at sea).

Lord Cherwell, P.C., F.R.S. : Paymaster-General

On July 5 in the House of Lords, Lord Cherwell made a vigorous attack on the way in which research on, and development of, atomic energy was being conducted in Great Britain. Lord Cherwell has now been appointed to the office of Paymaster-General in the new Government headed by Mr. Winston Churchill, and has been made responsible for the supervision of research and production in connexion with atomic energy, and also for the Prime Minister's statistical branch. It is worth recalling some of the points made by Lord Cherwell in the House of Lords debate. He referred to the impending retirement of Lord Portal from the post of director of atomic energy, and urged a complete change of organization. Civil Service methods, he said, were inadequate for the task, and the scientific men and engineers required were not forthcoming because they hesitated to commit themselves in a service where their work would always be subject to Civil Service administration. He asked for the transfer of work on atomic energy from the Ministry of Supply, which hitherto has been responsible for it, "to a special organization under the direct control of the head of the Government". His present appointment suggests that Lord Cherwell will now be able to put his views into practice, though such drastic changes in the control of a large body of scientific workers and others must clearly take a little time. Since he has a seat in the Cabinet and he is to have an office at 11 Downing Street, he will have easy access to the Prime Minister. Lord Cherwell is a man of energy and determination, and can be counted upon to see that atomic energy research and development in Great Britain receive the attention so vital a subject warrants.

Rockefeller Grant for Chemistry in the University of Oxford

The Rockefeller Foundation of New York has made a grant to the University of Oxford of £10,000, to be expended over four years, for the Dyson Perrins Laboratory in aid of research in organic chemistry sponsored or directed by the Waynflete professor of chemistry, Sir Robert Robinson. The chief topics of such investigations at the present time are: (1) degradative and synthetic studies of alkaloids, plant colouring matters, and certain other natural products; (2) study of the lipins of tubercle bacilli, especially the fatty-acid constituents; (3) isolation of a differential growth-inhibiting factor present in malt and wheat-middlings; (4) synthesis of steroids other than cortisone (this latter is covered by a grant from the Nuffield Foundation); (5) general studies of organic chemical reactions.

The Battelle International Institute

The Battelle Institute, Columbus, Ohio, the well-known American industrial research foundation, proposes to establish an international industrial research institute to serve European industry, on a non-profit basis, through science and technology. The new body, to be known as the Battelle International Institute, will establish research investigations in existing research institutes of Europe and in European universities and technical schools. It will also operate its own laboratories on the Continent. As with the parent organization, financial support for these activities will be derived from industrial sponsorship, from endowment, and from income from patents owned by the Battelle Institute. It will conduct research in the fields of applied chemistry and physics, metallurgy, fuels, ceramics, electronics, theoretical and applied mechanics, the engineering sciences and agriculture. Mr. John S. Crout, for many years assistant director of the Battelle Institute, has been appointed executive director of the new Institute.

Cultural Anthropology of the Rodiyas of Ceylon

The Rodiyas of central and southern Ceylon are a primitive tribal group, fifteen hundred strong, who have become partly incorporated in Sinhalese society as a caste of drum-makers and beggars. A brief account of them by M. D. Raghavan, "Cultural Anthropology of the Rodiyas" (Ethnological Survey of Ceylon, No. 1: *Spolia Zeylanica*, 26, Pt. 1, December 1950), is the first of a series of studies of the lower castes in Sinhalese society to be undertaken as part of the Ethnological Survey of Ceylon. It describes Rodiya myths of origin; habitat and village organization; daily life, crafts and methods of begging; rites at birth, marriage and death; and peculiarities of Rodiya dialect. Suggestions are offered for Rodiya education and for their further assimilation into Buddhist society. Of interest is the Rodiya myth of descent from Navaratne Valli, a Sinhalese princess who lost her caste through eating human flesh, and the comparison drawn between this mythical ancestress and the Kerala goddess Bhagavadi.

Catalogue of Kenya Timbers

The Government of Kenya has published a "Catalogue of Kenya Timbers", prepared by S. H. Wimbush, of the Forest Department (pp. 69;

Nairobi: Government Printer, 1950; 2*s.* 6*d.*). The author gives a brief description of Kenya Colony, with an area of 219,700 sq. miles, of which only one-third has a soil and climate suitable for normal human habitation. The south-western third of the Colony is made up of the Highlands, about one-tenth of which, that is, about 6,500 sq. miles, is believed to be forest. Although the climate of the Highlands is of a tropical nature, it has widely different extremes ranging from the alpine flora of snow-capped Mount Kenya to semi-tropical rain forest in the Lake Victoria basin. There are then two main divisions of forest in the Highlands: mountain forests which are made up of rain, coniferous, bamboo, and semi-evergreen forests; and semi-tropical rain forests. In addition, there are the lowland or coast forests comprising low and rain forest, lowland dry forest and lowland savanna woodland. Brief notes on the characteristics of these forest types are followed by a few general notes on Kenya timbers. Finally, there are indexes to botanical, English and trade names, and to native names with the botanical equivalents. The main purpose of the handbook is achieved, the trees mentioned being given alphabetically with the following details: local names, distribution, frequency, the timbers and uses. Handbooks of this type are invaluable to all forest officers working in tropical areas.

Industrial Microscopy

AN exhibition of "How Industry is Using the Microscope" has been arranged by the Royal Microscopical Society (Industrial Section), to be held on November 21 in the Great Hall, British Medical Association House, Tavistock Square, London, W.C.1, by kind permission of the British Medical Association. The exhibition will be opened by Mr. A. J. Philpot, director of the British Scientific Instruments Research Association, at 2.30 p.m., and will remain open until 9.30 p.m. Some forty exhibitors are taking part, including research associations and university departments as well as the research departments of a number of industrial firms and the Department of Scientific and Industrial Research. The exhibits cover a wide range and can be classified as concerning: mining and power; metallurgy; glass and ceramics; paint; paper, rubber and fabrics (including leather); photography; food and agriculture; pharmacy; biology. The various modern forms of optical microscopy are represented in addition to electron microscopy. Apparatus and techniques of general and special application are being demonstrated as well as surface profile techniques for electron microscopy. The exhibition is well illustrated by photomicrographs and electron micrographs. It is open to all, and the catalogue of exhibits and further information can be obtained from the Assistant Secretary, Royal Microscopical Society, Tavistock House South, Tavistock Square, London, W.C.1.

Royal Society of Edinburgh: Officers

OFFICE-BEARERS and members of council of the Royal Society of Edinburgh have been elected as follows: *President*, Prof. James Kendall; *Vice-Presidents*, Prof. Arthur Holmes, Prof. W. O. Kermack, Prof. E. T. Copson, Prof. J. H. Gaddum, Sir Robert Muir and Prof. James Ritchie; *General Secretary*, Dr. J. E. Richey; *Secretaries to Ordinary Meetings*, Prof. J. Norman Davidson and Dr. John E. Mackenzie; *Treasurer*, A. W. Young; *Curator of Library and Museum*, Dr. Douglas Guthrie; *Councillors*, Prof. T. Neville George, Prof. J. W. Heslop Harrison, Dr. C. E. Lucas, Prof. M. G. Say, Prof. W. M. Smart, Prof. J. F. Allen, Prof. A. Murray Drennan, Dr. E. Wyllie Fenton, J. M. Ross, Prof. C. M. Yonge, Prof. N. Feather and Sir Godfrey Thomson.

Announcements

CAPT. CYRIL DIVER, director-general of the Nature Conservancy, is to retire next autumn. A small committee under Sir Arthur Tansley, chairman of the Conservancy, is considering the problem of finding a successor to Capt. Diver.

MR. S. S. C. MITCHELL has been appointed controller of guided weapons and electronics in the Ministry of Supply, in succession to Air Chief Marshal Sir Alec Coryton. Mr. Mitchell, who is forty-nine years of age, will be in charge of all work in research, development and production of guided weapons in Britain. He will also undertake responsibility for the direction of the Ministry of Supply's work on electronics research, development and production.

DR. A. H. BUNTING, who held until recently the post of chief scientific officer with the Overseas Food Corporation (see p. 804), and who was responsible, from the inception of the groundnut scheme in Tanganyika in 1947, for the agricultural research services there, has been appointed to the Research Division of the Sudan Ministry of Agriculture. He is to be in charge of a new research station for investigating the agricultural potentialities of the central rainlands area of the Sudan. Dr. Bunting was trained at Johannesburg and Oxford (as Rhodes Scholar for the Transvaal, 1938) and has held appointments at Rothamsted Experimental Station, and with the Human Nutrition Research Unit of the Medical Research Council.

THE Department of Scientific and Industrial Research (Charles House, 5–11 Regent Street, London, S.W.1) is holding an international symposium on the organization of scientific and industrial research, which will take place in London during November 12–15. All sessions will be held in the Council Room, Lancaster House, London, S.W.1, with the exception of the third session, on "Sponsored Research", which will be held at the National Physical Laboratory, Teddington. Representatives from the following countries will be attending the symposium: Austria, Belgium, Canada, Denmark, France, Germany, Greece, Ireland, Italy, Netherlands, Norway, Sweden, Switzerland and the United States.

THE Science Section of the Society for Cultural Relations between the Peoples of the British Commonwealth and the U.S.S.R. has arranged a meeting to be held in the Anatomy Theatre, University College, London, W.C.1, on November 16 at 7 p.m. on "Some Aspects of Biological Research in the Soviet Union, 1948–1951". The chairman is Dr. Sidnie Manton, and other speakers are: Dr. A. Morton on "The Role of Environment in Plant Development"; Dr. R. Trim on "Enzymes and the Living Cell"; Dr. D. Ross and Mr. D. Newth "On Animal Embryos and Cells"; Prof. J. D. Bernal on "Relation between Living and Non-living Matter". Tickets of admission (1*s.*; S.C.R. members 6*d.*) can be obtained from the Society, 14 Kensington Square, London, W.8. It is hoped that this meeting may lead to regular annual surveys of Russian work in specific fields.

RESEARCH AND DEVELOPMENT IN BRITISH COLONIES, 1950–51

TO those annual reports of research and development in British Colonies which were last year collected under the title "Colonial Research" there have now been added reports for 1950–51 from the Tsetse Fly and Trypanosomiasis Committee, the Colonial Fisheries Advisory Committee and the Director of the Anti-Locust Research Centre. The present omnibus volume covering 1950–51* thus includes, besides these three reports, the annual report of the Colonial Research Council, the eighth annual report of the Colonial Products Research Council, the seventh annual report of the Colonial Social Science Research Council, the sixth annual reports of the Colonial Medical Research Committee and of the Committee for Colonial Agricultural, Animal Health and Forestry Research, and the fourth annual reports of the Colonial Insecticides, Fungicides and Herbicides Committee and of the Colonial Economic Research Committee. The broad background against which all this work is carried out and a general picture of the work itself is contained in the earlier report, "The Colonial Territories (1950–51)" (see *Nature*, October 20, p. 691). The present report gives the fuller details which the scientific worker expects, together with the particulars of membership of the several councils and committees and lists of publications.

Appended to the report of the Colonial Research Council is a list of research schemes—including fifty-seven new schemes and some sixty supplementary ones made during the year—and of the grants allotted from Colonial Development and Welfare funds. The total of £2¼ millions is the highest annual figure recorded, and brings the grant for research schemes since 1940 to about £10¼ millions. After deductions for unspent balances, etc., the net expenditure and commitment on March 31, 1951, was about £9·6 millions, of which slightly more than £9·3 millions is chargeable against funds provided by the 1945 and 1950 Acts, and to this must be added some £2 millions provided by Colonial governments or industry. The actual disbursement of £1,406,651 during the year is the highest recorded, and indicates that major schemes which have been hampered in their progress by scarcity of scientific personnel, labour, building material and equipment are now getting well under way. About 31·5 per cent of the gross allocation has been for agricultural, animal health and forestry schemes, 14·4 per cent for fisheries research, 13·7 per cent for medical research, 11·9 per cent for tsetse and trypanosomiasis research, 8·4 per cent for social science and economic research, 6·3 per cent for insecticides research, 4·6 per cent for research sponsored by the Colonial Products Research Council, 3·3 per cent for anti-locust research and 5·9 per cent for miscellaneous schemes. Major schemes approved during the year were £150,000 for the establishment of the West African Trypanosomiasis Institute and its maintenance for five years; a further £134,745 for the West African Fisheries Research Institute; £135,000 capital expenditure for the establishment of the East African Medical Survey and Filariasis Research Unit; £126,048 for the East African Institute of Social Research for five years; £200,000 for the maintenance for five years of the East African Tsetse and Trypanosomiasis Research and Reclamation Organization; £280,000 for the establishment and maintenance for five years of the East African Central Trypanosomiasis Research Institute; £263,000 for the East African Veterinary Research Organization; £217,228 for the promotion of agricultural research in Northern Rhodesia; and £260,000 for the establishment of a Marine Fisheries Research Station in Singapore.

Commitments against the £13 millions for Colonial research schemes allotted from the additional funds made available by the 1950 Colonial Development and Welfare Act reached approximately £8·3 millions by the middle of 1950, and in December 1950 the Colonial Research Council recommended that the balance should be apportioned between the various fields of research as follows: general reserve, £425,000; agriculture, animal health and forestry research, £1,300,000; work sponsored by the Colonial Products Research Council, £200,000; anti-locust research, £100,000; insecticides (including fungicides and herbicides) research, £550,000; tsetse and trypanosomiasis research, £425,000; fisheries research, £475,000; medical research, £600,000; social science research, £325,000; economic research, £100,000; and miscellaneous research (including industrial and engineering), £200,000. The Council also endorsed a proposal of the Colonial Office that the various research committees and councils should be asked to make recommendations as to the most profitable use of their funds apportioned to their respective fields to meet all new money required during the next five years, including provision for the research of important schemes.

The Scientific Council for Africa South of the Sahara has now been duly established, with Dr. P. J. du Toit as chairman and Dr. E. B. Worthington as secretary-general, and held its first meeting at Nairobi during November 1950. During the year an American hydrologist and engineer were engaged to survey flood conditions on the Kafue Flats in Northern Rhodesia, and a malacologist was secured to investigate the schistosome-transmitting snails in West Africa. A fourth scientific worker has been assisting in locust research at Cambridge. A further survey was made by the African Studies Branch of the Colonial Office of racial differentiation in the laws of all the African territories, and arrangements have been made for the reproduction of a bibliography of published sources relating to land tenure in the South-East Asia and Pacific Colonial territories compiled by the Colonial Land Tenure Advisory Panel. The report of the Colonial Building Research Liaison Officer on his visit to Africa in the autumn of 1949 has been endorsed generally by the Council. The report emphasized the need for encouraging the better use and improved manufacture of local materials and more economical building design. Problems which require urgent study include the behaviour of materials in tropical climates, the development of material manufactures and methods of construction suitable for African conditions, the design of buildings for comfort in hot climates, and low-cost housing for the African urban population. Research is also needed into the penetration of moisture through building materials and the fortification of native materials to resist insect and mould attack. A manual relating to the protection of buildings and timber against termites has been published. A census was held in Bermuda during October, and in Lagos in February, 1950. Recruitment of staff for the Directorate of Colonial (Geodetic and Topographic) Surveys made progress, and field survey work was maintained mainly in Africa, where the Royal Air Force continued air-photography in East, Central and West Africa. Mapping increased and considerable progress was made in the investigation of mineral deposits. Some fifty-two additional geologists, geophysicists and chemists were appointed during the year, and the universities are now being asked to extend their interest in Colonial geological research. In meteorology the principal development has been the progress towards a West Indies Meteorological Service, covering the West Indian Colonies and the Bahamas, with its headquarters in Trinidad (see also *Nature* of November 3, p. 769); but progress has also been made in the programme of *radiosonde/* radar wind stations and the facilities they will provide for the study of upper-wind conditions. The Colonial Road Research Liaison Officer visited Kenya, Uganda, Tanganyika and Zanzibar during September–October 1950. A report on this visit will shortly be issued. This visit has led to the conclusions, among others, that the more technical road problems of East Africa are broadly similar to those of West Africa, but are aggravated by the greater prevalence of poor-quality soils and roadstones, and that research on Colonial soils and roadstones, and indigenous materials such as *karkar*, coral, soda, wood-tar, and agricultural wastes, and to determine the minimum thickness and quality of road suitable for Colonial conditions, is urgently needed.

Colonial Research 1950–51: Reports of the Colonial Research Council, Colonial Products Research Council, Colonial Social Science Research Council, Colonial Medical Research Council, Committee for Colonial Agricultural, Animal Health and Forestry Research, Colonial Insecticides, Fungicides and Herbicides Committee, Colonial Economic Research Committee, Tsetse Fly and Trypanosomiasis Research Committee, Colonial Fisheries Advisory Committee, Director, Anti-Locust Research Centre. (Cmd. 8303.) Pp. 243. (London: H.M. Stationery Office, 1951.) 6s. 6d. net.

The report of the Colonial Products Research Council again consists of a general part and a more detailed review of some research work in progress. Much attention has been given to the fermentation of the cocoa bean, and it has been established that the predominant species of yeast in cocoa beans commercially fermented in Trinidad and Grenada is *Candida krusei* (A. Cast.) and that *Saccharomyces* species never represent a significant percentage of the total yeast microflora. The observation that the chocolate flavour develops after drying and roasting if aseptic ripe pods are left for some days in dilute solutions of either acetic acid or sodium acetate (but not citric or phosphoric acid) at 48° C. may prove of immediate industrial value. Work on the antibiotic 'comirin' is continuing, particularly with the view of utilizing it as a fungicide or in the protection of paper, canvas and paints. The Colonial Microbiological Research Institute has also investigated the red root disease of West Indian limes and the artificial cultivation of the edible mushroom, *Volvaria esculenta, Bresadola*, and at the University College of the West Indies Prof. C. H. Hassall and Miss L. Wong have shown that the antibiotic, monamycin, separated from a strain of Meredith's actinomycete, is not identical with musarin.

In the work at the University of Birmingham under Prof. M. Stacey more attention has been directed to the action of bacteria on sugar and other carbohydrates. Prof. Stacey's observation that ultrasonic sound waves can degrade the highly polymeric dextran obtained by the action of bacteria on sugar to give the blood plasma substitute previously prepared by acid hydrolysis has been applied in a completely new manufacturing process for this substance. The structures of various ethylidene derivatives of *d*-mannitol have been elucidated by G. T. Bruce, and a series of trifluoroacetyl derivatives of amino-sugars possessing unusual properties prepared by Dr. C. M. Tatlow are being further investigated. A detailed study of sugar-cane wax isolated from the filter muds of all the sugar estates in the West Indies is being made in collaboration with Prof. L. F. Wiggins, of the Imperial College of Tropical Agriculture, Trinidad, and a method for the purification of the wax is being tried on a pilot-plant scale, as is a method for the manufacture of lactic acid. A high grade of cellulose has been obtained by Prof. Stacey by the action of bacteria on sugar, molasses and effluents containing sugar. The examination of the pharmacological action on the nervous system of sugar derivatives prepared by Prof. Wiggins and his collaborators indicates that, with one exception, the seventy pyridazone derivatives screened are unlikely to be suitable for clinical trial. In Prof. Stanley Peat's laboratory at the University College of North Wales, Bangor, the complex system of enzymes involved in the metabolism of starch in the higher plants has been further studied.

Considerable progress has been made in the study of the thermal polymerization of drying oils, and the study of the component glycerides in *Stillingia* oil has been completed, as well as some further studies on deca-2 : 4-dienoic acid and its derivatives. Trials in different areas in Australia have demonstrated the marked effect of climatic conditions on sunflower seed oils, and sufficient information has now been obtained from the experimental plots to justify the Director of Agriculture, Nigeria, starting the cultivation on an area of two hundred acres of the vine, *Tetracarpidium conophorum*, the oilseeds from which provide the conophor oil in which the paint industry is interested; but although the prototype machine for decorticating candlenuts (*Aleurites triloba*) gives a satisfactory separation of shells and kernels, the latter are damaged to an extent which renders them unsuitable for export. Work has continued on plants of possible medicinal and insecticidal value: a study of the essential oil from the wood of *Brachylaena hutchinsii* has been completed, and the structure of the phenol, chlorophorin, present in *Chlorophora excelsa* wood established. Experiments on the purification of the germination factor for *Striga hermonthica* have been actively pursued at the Universities of Leeds and Cambridge. Examination of samples of the oleo-resin from *Pinus caribaea* (British Honduras) have shown that the oil of turpentine and resin are of excellent quality.

The seventh annual report of the Colonial Social Science Research Council estimates that a little more than £100,000 remains available for the next five years for new projects and contingencies in this field. While recruitment of junior research staff improved, difficulty is still being experienced in recruiting sociologists qualified to undertake field demographic studies and urban surveys, and senior men for appointments of two or more years. Special efforts have been made to associate the staff of university colleges in the Colonies with the work of the institutes of social and economic research. Besides the organization by University College, London, of anthropological investigations in the Jos

Plateau and Cross River areas, the two studies of the social structure of an Indian community in Fiji and of the development of social welfare services in Tonga (sponsored by the Research School of Pacific Studies of the Australian National University) and the social science research financed by the University of Malaya and the University College of the Gold Coast, some social science projects have been sponsored by Colonial governments without assistance from Colonial Development and Welfare funds. Research into the grammar and structure of the Somali language, for example, has been carried out by the Director of Education, Somaliland Protectorate; the Tanganyika Government has employed three sociologists, who were to investigate land usage and associated problems in the highland areas of the Northern Province, make a two-year intensive study of the Sukuma tribe, and also a study of the Makere tribe of the Southern Province. The Government of the Gold Coast has financed further research into the teaching of English and into customary land tenure in the northern territories, while the Institute for Medical Research, Malaya, has made studies into the social and economic factors in food consumption, in conjunction with clinical and dietary investigations into malnutrition. The Ethnographic Survey of Africa by the International African Institute has made considerable progress; the survey of the Northern Bantu linguistic border was nearing completion and two sections of the survey of the languages of Africa (Berber languages of North Africa and languages of West Africa) were in the press. Besides brief notes on various socio-economic, ethnographic and anthropological studies in progress in Africa, in South-East Asia and the Pacific and the Caribbean, including also some investigations on psychological testing, the report includes as appendixes reports on work of the Institute of Social and Economic Research of the University College of the West Indies, the West African Institute of Social and Economic Research, which began operations in October 1950, the East African Institute of Social Research, which started work in May 1950, and the Rhodes–Livingstone Institute; appendixes also deal with research under the auspices of the University of Malaya and with research in social sciences at the University College of the Gold Coast and in education at Singapore. The policy and proposed programme of research of the West African Institute are given in full.

All the main schemes under the Colonial Medical Research Committee continued during 1950–51; but the sixth annual report again records inadequate recruitment. Only £600,000 was available from Colonial Development and Welfare funds for continuance of these and for the initiation of new schemes up to 1956, and the programme is under review in the light of this allocation. The Filariasis Research Unit established at Mwanza, Tanganyika, has now been fully staffed and has extended its surveys of filarial infections in the area. Studies on the chemotherapy of bancroftian filariasis have confirmed the high tolerance of the African for doses of the piperazine derivative, 'Hetrazan'. Investigations on loiasis in the Cameroons continued, and in south-west Nigeria a study of the ecology of the local species of *Cyclops* (the copepod crustaceans dwelling in ponds and streams which serve as intermediate hosts to the guinea worm) and a survey of the infection in the area have been commenced. Reasonably good results were obtained in the first twelve months of an experiment in the control of malaria in four valleys in Negri Sembilan, Malaya, in which all houses in one valley were sprayed with DDT, in another with 'Gammexane', while in a third proguanil was distributed weekly to the population. Studies of the effectiveness of DDT and 'Gammexane' against Malayan mosquitoes have also been made, while in North Borneo, besides studies of the repellent effect of DDT to *A. leucosphyrus*, the entomological, spleen and parasite surveys required for the Tambunan experiment to determine whether malaria can be controlled by the localized clearing of jungle growing over *A. leucosphyrus* breeding places has continued. Malaria research in Jamaica has been directed chiefly to the study of the habits and infectivity of suspected malaria vectors, mainly *Anopheles albimanus*, and the distribution of anopheline bites among different human age-groups in relation to general problems of malaria transmission and epidemiology; in Trinidad investigations on outside-resting *A. aquasalis* were intensified, and others on the relative attraction of various animals for *aquasalis*, night activity and ecological studies of various types of breeding places were started. An investigation of the natural history of malaria in African infants in Nigeria was concluded, and comparative field trials on three groups of 245 African school-children naturally infected with *P. falciparum*, *P. malariae* and *P. ovale* showed that all malario-metrical indices decreased more rapidly in the chloroquine than in either the mepacrine or the proguanil groups.

Neither a director nor adequate scientific staff have yet been secured for the West African Virus Research Institute, Lagos, but at the East African Virus Research Institute, Entebbe, Uganda, a long-term programme of research on rickettsioses, with special emphasis on tick-typhus, has been commenced and research on the epidemiology of yellow fever has continued. Further work on the preparation of specific precipitin sera for the identification of blood-meals of insects was carried out at the Lister Institute, London, and the scrub-typhus field research unit of the Institute for Medical Research, Malaya, has completed a general survey of potential mammalian hosts and trombiculid mites, which has shown that the common giant rats (*R. sabanus*, *R. mülleri*) of the Malayan forest are the proper hosts of the vector-species group of mites, while the stream- and gulley-infesting species *R. mülleri* is the chief host of *Trombicula deliensis* itself in the forest. The Field Research Station, Fajara, Gambia, is now better placed to conduct its investigations into causes of ill-health and inefficiency among the rural African population and on measures likely to alleviate or eradicate them. In Malaya clinical trials of thiacetazone against leprosy are well advanced, and in Nigeria, following a study and assessment of the value of sulphone treatment, an attempt is being made to develop a simple, cheap and effective form of sulphone treatment suitable for wide use in such countries as Nigeria.

In the sixth annual report of the Committee for Colonial Agricultural, Animal Health and Forestry Research reference is made to the work under the East African Agriculture and Forestry Research Organization with systemic insecticides against rosette disease of groundnuts. Although initial infection was not prevented, the aphids carrying the virus were killed. Work on the sudden-death disease of clove trees has shown that the disease is due to more than one cause and in young clove trees is largely caused by a new and undescribed species of

Cryptosporella, which is also responsible for a high proportion of dieback in mature trees. Besides research on animal trypanosomiasis and particularly on 'Antrycide', research has been carried out on lapinized rinderpest virus. At the West African Cacao Research Institute, Tafo, investigations are proceeding into the diseases and pests of cacao, the agronomy of the crop, the breeding of improved types and problems of cocoa fermentation. At Rothamsted a survey of the occurrence of aluminium in the plant kingdom, including every family of flowering plant and vascular cryptogams, has shown that very strong accumulators of this element are confined to twenty, and moderately strong accumulators to twenty-eight, families.

Fuller space is given in this report to the work being undertaken by the Colonial Departments of Agriculture, Forestry and Veterinary Services, among which may be mentioned the investigations in British Guiana into the causes of loss in fertility of the 'pegasse' soils of the north-west; the study in the Gold Coast on the dieback disease of lime, and plant-breeding work in Kenya with wheat, maize, sorghum, barley and oats to produce disease-proof varieties of improved yield and commercial qualities, and in Tanganyika on coffee. The survey and collection of varieties of paddy have continued in Malaya, and the discovery in New Guinea of a tachinid parasite of the banana scab moth, *Nacoleia octasema* Meyr., offers the possibility of a biological method of controlling this pest. In Jamaica further work has been carried out on tick dip-fluids for cattle; besides cattle-management studies in Uganda, extensive field trials have been made of a copper preparation for seed disinfestation, and these have given promising results in the control of blackarm disease of cotton. Reports from the standing Sub-Committees for Cocoa Research, Soils and Stored Products Research are also included.

The fourth annual report of the Colonial Insecticides, Fungicides and Herbicides Committee, to which is appended an outline of the work of the Committee during 1947–50, emphasizes the high standard of the work of the Colonial Insecticides Research Team at Porton. The studies on aqueous suspensions of DDT particles in different size-ranges have yielded results which are important for the control of other insect pests besides adult mosquitoes, with which the work has already been done. An inverse relation has been established between particle size of insecticides and their initial contact-toxicity to mosquitoes and a similar relation between particle size and fumigant effect, and the work has been extended to include its effect on the persistence of volatile insecticides with the view of determining formulations giving the maximum initial and residual toxicity. Besides the sorption of solid insecticides by dried mud-blocks, a study has been made of the contact-toxicity to mosquitoes of deposits from aqueous suspensions of inert dusts impregnated with insecticides from other solutions. Promising results have been obtained in the incorporation of insecticides in resin surface coatings, and one containing 20 per cent DDT prevented for several months the fouling by barnacles of marine underwater wooden surfaces. At Silwood Park a detailed study was being made of the structure of insects to determine the mode of action of residual deposits, and also of the way in which insecticide particles are picked up by insects when moving over treated surfaces, while studies at Rothamsted have shown that at 110° F. DDT is rapidly lost by volatilization from crystalline deposits and that the presence of wax has little effect on the contact-toxicity of the glass plates. Final assessment of the results of the trials on the application of insecticides by aircraft against the tsetse fly is not yet possible, but under certain conditions and against certain species almost complete elimination of the tsetse population of a given area appears possible, although whether the method is economically feasible has yet to be proved. It has been necessary to abandon for the time being the project for establishing a West African Insecticide Research Unit. Final results on the treatment of African huts at Kasanje and Mbale, East Africa, for control of mosquitoes and malaria indicate that BHC applied at three-monthly intervals is the best insecticide to use.

The Colonial Economic Research Committee records in its fourth annual report that the study of the national income of Nigeria was initiated in the autumn of 1950, and a survey of the available data relating to Colonial dependence on imported foods has been completed. Arrangements were made in March 1951 for a pilot investigation of the value of sample market surveys as an aid to the promotion of industrial development in the Colonial territories. It is hoped to recruit suitable economists to undertake studies of the retail trade in Tanganyika, Nyasaland and Zanzibar and of capital investment in the Colonial territories generally.

The report of the Tsetse Fly and Trypanosomiasis Research Committee for 1950–51 is prefaced with some notes on the origin and past activities of the Committee. Its work on insecticides has now been taken over by the Colonial Insecticides, Fungicides and Herbicides Committee; and, when the Committee was reconstituted in 1949 and the directors of the East African Tsetse and Trypanosomiasis Research and Reclamation Organization and of the West African Institute for Trypanosomiasis Research were invited to join, the terms of reference were slightly amended and made to read as follows: "To consider and advise on the co-ordination of action, including research and reclamation, directed against human and animal trypanosomiasis".

Considerable progress has been made in studying the relation of the tsetse to its environment, and new techniques were being developed. Plans were being formulated for three schemes of experimental practical reclamation work, one in each of the East African Territories, and interesting results have been obtained in conjunction with the East African Veterinary Research Organization, with a programme of monthly and two-monthly prophylactic injections of 'Antrycide'. Close interest has been taken in the antimonial and arsenical compounds discovered by Dr. F. A. Friedheim for use in human trypanosomiasis, and, following satisfactory results with melarsen, further trials will be carried out.

The Colonial Fisheries Advisory Committee's report on Fisheries Research for 1950–51 refers to the almost complete lack of trained and experienced research workers which has delayed implementation of the research programme. A good supply of candidates for fisheries research studentships to be awarded in 1951 became available, however, and from 1952 the staff situation should be easing. At the Inter-territorial Fisheries Research Station at Jinja, on Lake Victoria, an intensive study of the growth of the phytoplankton has been started as well as of the identification and life-histories of snails and of their parasites, and on growth-rates and breeding of several species of fish. Research at the West African Fisheries Research Institute was about to begin.

The report of the Director of the Anti-Locust Research Centre on locust research and control for 1950–51 reviews the advisory activities of the Centre, which are chiefly connected with regional anti-locust organizations, as well as that of the Desert Locust Control Executive Committee, and with the research being carried out on the taxonomy of locusts and grasshoppers, field investigations on the behaviour of adult desert locusts and on methods of control. Extra-mural researches mostly fall in four overlapping groups: three of them, namely, those investigations in biochemistry, physiology or behaviour which relate to phase phenomena, phenomena migration or to population dynamics, are only just beginning; the fourth group relates to the destruction of locusts by insecticides and machinery. A 20 per cent solution of dinitro-*o*-cresol has proved very effective for aircraft work, but baiting remains the principal method of control.

TECHNIQUE OF ELECTRON MICROSCOPY

CONFERENCE AT ST. ANDREWS

THE Electron Microscopy Group of the Institute of Physics held a conference in St. Andrews University during June 19–21, which was attended by about eighty scientific workers On the first day three symposia were held: recent experiences in the cutting of thin sections; critical testing of instrument performance; and replica techniques. This was followed by a few short original papers. The second day was entirely devoted to the reading and discussion of papers.

M. S. C. Birbeck opened the session on section cutting by discussing modifications to be made in histological technique in order to cut sections thin enough for electron microscopy. Embedding and fixation were particularly dealt with, as it is in these preparative processes that the main difficulties now lie; the actual cutting of suitably prepared blocks is no longer a matter of special difficulty. The modified Cambridge rocking microtome will cut to 0·2 μ, and some Continental makers are producing instruments to cut even thinner sections than this.

It is desirable to embed the tissues in a harder medium than usual, and Mr. Birbeck favours 'ester wax', though Dr. C. E. Challice prefers the purer diethylene glycol distearate, and Prof. L. H. Bretschneider uses a wax mixture including carnauba wax. Fixatives which are suitable for optical preparations may fail for electron microscopy because they precipitate the protein in a fine form which shows spurious structure in the electron microscope size-range. There are exceptions, however, and the most successful fixatives for this purpose are those based on osmic acid and potassium dichromate. Altmann's mixture is specially recommended.

Dr. C. E. Challice opened the discussion and was in general agreement with Mr. Birbeck's methods, differing principally in the knife-blade he uses and in methods of removing the ester wax from the section when cut. Birbeck sublimes the wax in the electron beam itself, but Challice finds that this leaves a 'fixed' residue and prefers to warm the specimen *in vacuo* before exposing it to the beam.

Dr. J. Nuttings's paper opening the session on replica techniques was read for him by Dr. A. F. Brown. After ten years of development, the electron microscope is beginning to give results of real value to metallurgists; and this is happening, not because of special advances in technique and resolving power, but because of the accumulation of experience and data from the use of plastic replica techniques at moderate resolving power and magnification.

Comparison of dry-stripped 'Formvar' replicas with optical micrograms of the identical areas of the surface (made possible by a method developed by E. D. Hyam) show that at least in the optically resolvable range these replicas are completely reliable. Dr. G. L. J. Bailey, in discussion of this paper, expressed the opinion that the biggest problem before the electron microscopist in the metallurgical field is to persuade the classical metallurgist to accept his results; but he was able to cite instances where the electron microscope has proved trustworthy when the conventional optical methods have given misleading results.

Replica methods giving higher resolving power than the simple plastic replica are available or are being developed, but cannot compete with the speed and ease of the dry-stripped 'Formvar' process. Such are the method of polymerizing a monomer *in situ* to form an intermediate cast (in a two-stage process), and, as J. B. Le Poole mentioned, the use of an evaporated silver intermediate cast with silicon monoxide for the final replica, which is said to have a grain size of atomic dimensions and give maximum resolution. The resolution of the simple plastic replica, also, can be improved by preshadowing the metal surface; but there is sometimes difficulty in stripping the shadowing metal, and the discussion showed that the conditions under which this occurs are not understood. A paper by A. W. Agar and R. S. M. Revell, read later in the conference, discussed plastic replicas of ferrous specimens, and suggested that, though the major features are reliably pictured, some fine detail, especially on ferrite grains, is probably spurious and due to the etching process.

The basis of interpretation of replicas of some chromium–nickel steels was broadened by Dr. J. F. Brown and D. Clark, who isolated particles of sigma-phase electrolytically and investigated their crystal structure by electron diffraction (of individual particles selected from the electron microscope field). Correlation of the particle shapes with features of the replicas was possible. J. Trotter has observed two intermediate nitride phases in alpha-iron in addition to the well-known Fe_4N.

The interesting work of Drs. I. M. Dawson and V. Vand on spiral growth of crystal faces, particularly of the paraffin *n*-hexatriacontane (see *Nature*, 167, 476; 1951) was reported to the meeting, and one or two points of general interest to electron microscopists emerged. Gold-manganin is mobile in the electron beam on a paraffin surface and therefore cannot be used as a shadowing metal; palladium is satisfactory for this purpose. The graphitization of the paraffin in the beam is not instantaneous, and paraffin electron-diffraction patterns can be observed for about five minutes before they degenerate into diffuse rings. There was some discussion on the stability of these materials in the beam, and it seems that chemical structure is at least as important as melting point in determining their resistance; thus a paraffin of melting point 74° C. may be quite stable, whereas an aromatic hydrocarbon of melting point 200° C. may polymerize.

A spongy growth of silica in a furnace containing zirconium silicate bricks was shown by Mr. G. A Bassett to be in the form of long fine filaments, each of uniform diameter in the range 100–600 A. This curious form of growth appears to be associated with the vapour phase, as a similar growth of silicon filaments is observed in the action of silicon tetrachloride on zinc. In the case of the silica the X-ray picture shows the filaments to be vitreous.

S. F. Ward reported an instability of siliceous material in the electron beam, having observed that the diatom *Synedra fulgens* shrinks by 5–10 per cent in length on first exposure in the microscope, though after this it becomes stable. The striation-spacings in this diatom show a coefficient of variation of up to 9 per cent, so that if it is to be used for magnification calibration it must first be stabilized and then calibrated optically over the identical region used in the electron microscope observations.

H. L. Nixon has extended the method of concentration estimation by particle counting, first described by Williams and Backus, by using tomato bushy stunt virus instead of polystyrene latex as his standard reference particles. The sprayed droplet size is kept small so that a trace from an evaporated drop is only 2–3 μ in diameter and can be photographed entire at a sufficient magnification to enable one to distinguish bushy stunt virus from other particles in the 10–50 mμ range, while the number of bushy stunt particles can be large enough to give adequate statistical accuracy from counts of only a few traces.

Some experiences of the effect of salt in the purification of vaccinia virus were reported by Drs. C. E. Challice and A. S. McFarlane. Slow flocculation by sodium chloride of a well-washed preparation gives very clear and sharp virus particles as seen in the electron microscope, but similar treatment of less well-washed material results in a non-removable fine granular deposit becoming attached to the virus bodies.

Dr. R. Reed described some work, carried out in Prof. W. T. Astbury's laboratory at Leeds, in collaboration with Dr. L. Hoyle, on the human influenza virus. Ether treatment causes the virus bodies to break down into smaller particles, which form two groups, one showing antigenic activity and the other agglutination properties. It is suggested that the virus-replicating units may be small protein macromolecules which later aggregate to form the virus elementary bodies. Dr. Reed also mentioned work on fibrous components of the human skin, and showed slides illustrating the changes in collagen and elastic tissue in various pathological conditions. Subcutaneous lesions in rheumatoid arthritis have been examined, and the collagen shown to be partly degraded in the intermediate regions and reduced to debris in the badly diseased regions. Preliminary findings on the action of adrenotropic hormone (ACTH) and cortisone on the fibrinoid regions of the diseased tissue were also touched upon.

Work on the cell wall of *Staphylococcus aureus* by Dr. I. M. Dawson and H. Stern makes it very probable that this is of a polysaccharide rather than a protein nature. The apparent disappearance of the cell walls of the intact cells when the organisms are treated with cetyl trimethyl ammonium bromide (CTAB) is ascribed to swelling of the cytoplasm into such intimate contact with the enclosing wall that the latter is no longer separately distinguishable.

The problem of sterilization of film-covered electron microscope grids, before inoculation with slow-growing organisms, has been solved by R. W. Horne by exposing them to ultra-violet radiation; this does not damage the thin nitrocellulose or 'Formvar' film.

The stages of development of the spermatozoon of the spider beetle *Ptinus tectus* were described by Drs. J. Długosz and J. W. Harrold. The mature sperm is unusual in having neither a head nor a nucleus in the ordinary sense; it is of filamentous form, with the hereditary material distributed along the central axis.

Dr. H. J. Woods, with S. M. Mukherjee and J. Sikorski, following the work of Rånby and Ribi, have examined the products of sulphuric acid disintegration of various cellulose textile fibres and find very similar elongated tablet-shaped particles in each case, though the dimensions (20–40 A. thick by 80–160 A. wide) vary somewhat from fibre to fibre. This represents a disintegration beyond the more familiar fibrillar state. Similar tablets are obtained from mercerized materials. Films made by depositing the tablets from suspension show a preferred orientation of the 101 planes parallel to the surface, and the density of such a film is greater than that of the native cellulose of the original fibre, as would be expected if the particles represent the more highly crystalline portions of the cellulose.

The session on critical testing of instrument performance was opened with a lecture by M. E. Haine. Low resolution may often be due to some coarse and easily detected defects, like stage drift or electrostatic charges. Removal of these more obvious faults may still leave a lack of resolution, and Mr. Haine gave a list of possible causes and the means of their detection. Thus, astigmatism can be detected by observing zinc oxide crystals, or, if less prominent, by the observation of the Fresnel pattern near the focus, as used by Hillier, etc. For the most exacting requirements, the Fresnel fringe test with coherent illumination, as described by Haine and Mulvey, can be applied. Mr. Le Poole mentioned his method of locating charged-up areas by forming images of them on the observation screen. Lens current and high-tension variations can be determined from the change in the electron diffraction pattern.

Dr. H. J. Woods and J. Sikorski read a short paper on the filament life in the Metropolitan-Vickers *E.M.*3 instrument. They have found an average life of 15 working hours (at 75 kV.), but filament life appears very dependent on the experience of the operator. J. B. Le Poole and A. C. van Dorsten described a short focal-length objective. From certain theoretical considerations they have found that an objective of 0·8 mm. focal length (at 80 kV.) should be possible. Experiments with soft-iron pole-pieces have confirmed this, giving the predicted focal length. Slightly more favourable dimensions can be obtained with cobalt–iron pole-pieces. The advantage of such a short focal-length objective is its low chromatic aberration, which reduces the requirement for voltage and current stabilization.

A paper on the performance of high-voltage electron guns, as used in electron microscopes, was read by M. E. Haine and P. A. Einstein. It was shown that for a wide range of electrode geometries the theoretical limit of brightness, as predicted by D.

Langmuir, can be achieved if suitable bias-voltages for the shield electrode are chosen. The geometry of the gun is only important in determining the most economical working conditions, that is, lowest total current for maximum brightness.

Dr. G. Liebmann discussed magnetic projector lenses. The focal length of all symmetrical projector lenses can be represented by one single curve. All lenses can be operated at a point where they are free from radial distortion. Calculations agree well with Ruska's measured data. Certain results of use in practical lens design were combined by Dr. Liebmann in a design chart. Dr. C. E. Challice described a modification of the projector lens of the RCA *B*-type electron microscope, which turns the two-stage instrument in effect into a three-stage one, by replacing the standard pole-pieces of the projector lens by a double-gap pole-piece insert. In this way the usable range of magnifications can be greatly increased. A similar modification has been carried out by Dr. J. F. Brown and D. Clark on their Metropolitan-Vickers *E.M.2* instrument. They added a further excitation coil and replaced the existing pole-piece insert by a double-gap insert, adding also a diffraction diaphragm.

Dr. G. L. Rogers gave a talk on "The Elements of Diffraction Microscopy". He reviewed the principles of Gabor's proposals, and pointed out that each 'hologram' can be considered as a zone plate. Thus a definite focal length $\pm f$ can be ascribed to each hologram. f determines the image position, whereas the magnification of the 'reconstruction' follows from geometrical considerations.

D. G. DRUMMOND
G. LIEBMANN

MEDICAL EDUCATION IN TURKEY

ONE of the articles (which is written in English) by Prof. F. Nafiz Uzluk in the latest issue of *Acta Medica Turcica* describes the present state of medical education in Turkey (3, No. 1–2; June 1951).

The old medical education of the Moslem Turks living in Anatolia was based on the medical teaching methods of Jundi Shahpur, as it has been in other Moslem countries. According to this system of teaching, students were required to finish their primary and secondary education in privately owned medresses (religious schools or seminaries). After this they were sent to hospitals to get medical experience by familiarizing themselves with various diseases by the bedsides of patients. That was the general procedure to acquire both practical and theoretical knowledge in order to become a physician. At the end of his training a successful student who had proved his ability was granted a diploma.

Some individuals were fortunate enough to continue their studies in sciences other than medicine; these sciences were classified as theological, juridical or technical. If, in addition to medicine, a student could also continue his studies in one of these fields, he was granted the title of professor or judge. He also obtained the privilege of teaching in one of the medresses.

During the period of the Ottoman Empire, which lasted six hundred years, some of the Turkish physicians held offices as Kadies of Cairo or Istanbul or as military Kadies of Anatolia and Rumeli. Among them some were appointed as the grand religious leader (Sheyhulislam).

Suleyman the Magnificent, or the Law Giver, the Turkish Sultan who ruled in the sixteenth century, had built the famous mosque which was named after him with eight medresses surrounding it. One of these medresses was devoted to medical teaching, and each year eight students were awarded scholarships. In the records of a charity foundation these students are described as "danissments", a word corresponding to what is now called "assistant". In the same record are the words "muit", an Arabic word corresponding to associate professorship, and "muderris", corresponding to the full professorship of to-day.

The medical institute built by Suleyman the Magnificent lasted until 1860. Here a large number of physicians were trained and sent to many different parts of the Turkish Empire. In 1827 the Turkish Military Medical School was founded. In this institution at the beginning the teaching language was Italian, but later French was accepted in its place. This school lasted until 1909. The graduates served in the Army with appropriate ranks.

To make studies easier, in 1866 the Turkish language was accepted instead of French. In the same year another medical school was opened for civilians. These two schools continued in separate buildings until they were brought together in 1909 and a bigger institution came into being at Istanbul. The Medical Faculty of the University of Istanbul developed from this school.

Besides these schools, a surgical school was opened in Istanbul in 1831. This institution also provided many surgeons for the Turkish army and later was combined with the Military Medical School, which is still functioning.

In 1945 a new medical faculty was founded in Ankara as a part of the University. At present there are two medical faculties, one in Istanbul and the other in Ankara. The duration of studies before graduation is six years; entry is open to all without discrimination of any kind provided the candidate has reached the necessary standard of general education.

In 1951, 150 students were accepted by the medical faculty at Ankara; at present the general enrolment consists of 1,048 young men and 218 women. During 1945–50, 534 doctors graduated from the medical faculty of the University of Ankara, which thus provides an average of more than a hundred doctors a year.

At Istanbul, more than four hundred medical students graduate each year.

At present there are 7,349 medical men in Turkey. As the total population of the country is twenty-one million, 2,857 people are served by each physician. Besides the medical schools at Ankara and Istanbul there are two other advanced schools. One is the School of Dentistry, founded in 1909, and the other, the School of Pharmacology, founded in 1879. The duration of studies in these schools is four years.

In order to practise medicine and pharmacology in Turkey, a person must either graduate from one of the institutions described or from one of the well-known foreign faculties. Doctors of other nationalities are not allowed to practise medicine in Turkey, but some professors and specialists of foreign origin are given special permission; although they are not allowed to practise, they may be invited for medical consultations by Turkish medical men.

After further training a graduate of one of the medical faculties may specialize in one of the following branches: in internal diseases; surgery; neurology and psychiatry; gynæcology; pædiatrics; diseases of the ear, nose and throat; diseases of the eye; dermatology; neuropathology; urinary diseases; orthopædics; biological chemistry; pharmaceutics; microbiology; physio-therapeutics; anatomical pathology; radiology and radiotherapeutics; hygiene and medical jurisprudence. After acquiring both practical and theoretical knowledge and after passing a recognized examination he may become a specialist.

Besides this article the journal contains others in English, French and German. *Acta Medica Turcica* is owned and controlled by the Ankara University Medical Faculty and is edited by a Board appointed by the Council of the Faculty. It is devoted to the publication of original observations and investigations in various fields of medicine, and is published four times a year.

UNIVERSITIES OF GREAT BRITAIN

FINANCIAL AND POPULATION STATISTICS FOR 1949–50

THE publication entitled "Returns from Universities and University Colleges in receipt of Treasury Grant for the Academic Year 1949–50"*, issued by the University Grants Committee, is arranged in general on the same lines as in previous years, but a smaller format has been adopted. A new table gives for each university and university college comparative figures of income and expenditure in the year 1949–50 and the previous year. The chief features of the returns are the record number of students (85,421, compared with 83,690 in 1948–49), the continuing high proportion of assisted students (62,199 or 72·8 per cent, as against 61,655 or 73·7 per cent in 1948–49 and 55,539 or 70·7 per cent in 1947–48) and the increased dependence on Parliamentary grants, which represent 63·9 per cent of the recurrent income as against 59·2 per cent in 1948–49 and 57·8 per cent in 1947–48. There was again a welcome increase in the ratio of staff to students, the full-time teaching staff increasing by 540 to 7,930. The increase in staff was made up chiefly of 35 professors, 26 readers, assistant professors or independent lecturers, 126 senior lecturers and 329 lecturers.

Of the full-time students, 68,605 were reading for a first degree, 9,459 for a diploma, and 7,357, together with 4,080 of the 17,660 part-time students, were engaged in research or other advanced work; 63,157 full-time students were in England, 5,284 in Wales and 16,980 in Scotland; of these, 15,309 were at Oxford and Cambridge, 17,499 at London and 30,349 at other English universities and university colleges. Increases in numbers at the individual universities were not in general large, and there were small decreases at King's College, Newcastle upon Tyne, the Universities of Liverpool and Nottingham, Manchester College of Technology, University College of North Wales, Bangor, and the Universities of Aberdeen and Edinburgh. The proportion of full-time students residing in colleges and halls of residence was 22·8 per cent, as against 25·1 per cent in 1938–39, in spite of the substantial amount of new residential accommodation brought into use since the War, although the number in residence is greater (19,458 as against 12,555); 39·3 per cent were in lodgings and 37·9 per cent at home, the corresponding figures for 1938–39 being 33·2 and 41·7 per cent, respectively. There was a slight increase in overseas students compared with 1948–49: 3,387 full-time and 1,580 part-time students came from within the British Commonwealth, while a further 2,677 full-time and 1,316 part-time students came from foreign countries; these figures compare with 2,857 full-time and 658 part-time Commonwealth students and 2,356 full-time and 999 part-time foreign students in the last year before the War. Of the 24,331 students admitted for the first time in 1949–50 (a decrease of 495 on 1948–49), 21,574 were reading for a first degree and 2,757 for a diploma, and of those reading for a first degree 13,519 were nineteen years of age or more.

The distribution of students differed little from that in 1948–49, 43·6 per cent being in arts, 19·8 per cent in pure science, 16·6 per cent in medicine, 12·8 per cent in technology, 3·2 per cent each in agriculture and in dentistry and 0·8 per cent in veterinary science. Of the full-time advanced students, 37·7 per cent were in arts, 36·3 per cent in pure science and 12·9 per cent in technology. Only in agriculture was there a decrease in numbers (146) during the year, the increases in the remaining groups being arts 96, pure science 818, medicine 429, dentistry 177, technology 49, and veterinary science 308; 286 of these last were due to the incorporation of Glasgow Veterinary College into the University of Glasgow. Of the full-time students, 50,039 out of 66,068 men and 12,160 of 19,353 women, or 72·8 per cent of the total, were receiving assistance in the way of scholarships, exhibitions or other awards from public or private funds. The percentage for England as a whole was 76·2, for Wales 83·7 and for Scotland 56·7, compared with 76, 81·8 and 62·9 per cent, respectively, in 1948–49. For the provincial universities the figure (79·5) was intermediate between those for Oxford (82·2) and Cambridge (78·6), but higher than that in the University of London (66·9). Of the part-time advanced students, 45·1 per cent were in medicine and dentistry, 32·3 per cent in arts, 10·8 per cent in pure science and 10·8 per cent in technology.

The recurrent income of the universities and university colleges in the year under review amounted to £22,009,735, an increase of £3,853,157 on the previous year, parliamentary grants totalling £14,056,436 and representing 63·9 per cent of the total as against 59·2 per cent in 1948–49. Income from fees increased to £3,898,809, from endowments to £1,253,784 and from grants from local authorities to £1,008,128, but were only 17·7 per cent, 5·7 per cent and 4·6 per cent, respectively, of the total as compared with 20·6 per cent, 6·7 per cent and 5·0 per cent in the previous year; for England these percentages were 17·5, 5·8 and 4·8, respectively, for Wales 16·7, 2·1 and 6·9, and for Scotland 18·9, 6·3 and 3·0. The total income for English universities was £17,604,807, of which £6,348,424 was for the University of London, £2,003,845 for Cambridge, £1,566,547 for Oxford, £1,057,990 for Manchester, £940,779 for Durham and £914,963 for Birmingham. The total income for the University of Wales was £1,064,105 and for Scotland £3,340,823.

* University Grants Committee. Returns from Universities and University Colleges in receipt of Treasury Grant for the Academic Year 1949–1950. (Cmd. 8307.) Pp. 38. (London: H.M. Stationery Office, 1951.) 1s. 6d. net.

Of the total expenditure of £21,799,958, an increase of £3,777,864 on the previous year, administration accounted for 8·8 per cent, departmental maintenance 68·2, maintenance of premises 10·8, and miscellaneous expenditure 10 per cent. Capital expenditure met from reserves totalled £472,327, and allocation to reserve £270,993. Departmental maintenance included salaries of teaching and research staffs and payments for superannuation, the running costs of laboratories, lecture rooms, libraries and museums, and the supply of materials, apparatus, books, specimens, etc. Salaries and superannuation amounted to £10,546,346, and departmental and laboratory maintenance £3,272,900, as compared with £8,185,763 and £2,864,845 in 1948–49. Library expenditure, which amounted to £788,402, an increase of £155,147 on the previous year, is analysed in a separate table which shows that of this total £416,604 was for salaries and wages, £182,595 on account of books and £95,867 on periodicals. These figures all show increases on those for the previous year; while the percentage of university expenditure on libraries was still only 3·7 as against 3·4 in 1948–49, eleven universities, Oxford (£25,688), Cambridge (£13,969), Manchester (£8,499), Birmingham (£7,922), Liverpool (£6,022), Glasgow (£10,924), Edinburgh (£9,671), Aberdeen (£6,320), London (£5,806), Reading (£5,068) and Leeds (£5,778), as well as the London School of Economics (£5,515) and the School of Oriental and African Studies (£5,024), spent more than £5,000 on the purchase of books. Of these, Cambridge (£9,601), Glasgow (£7,421) and Oxford (£6,683) also spent more than £5,000 on periodicals.

PERSONNEL MANAGEMENT

IN a recent broadsheet published by the Institute of Personnel Management, G. R. Moxon examines the functions of a personnel department in an industrial undertaking.

The personnel department is a division within the management structure wherein men and women are employed to help to evolve and carry out the various policies of a company in matters affecting its employees. Following current industrial practice, the work of a personnel department is described under six headings: employment, wages, joint consultation, health and safety, employee services and welfare, and education and training.

There is, however, no model or standard personnel department because industry itself is so infinitely varied. British industry is largely made up of companies employing less than a hundred persons. No specialized department is necessary for so small a unit and, in all probability, one personnel officer, responsible to the head of the business, may adequately cover the normal personnel duties arising from the employment of anything from 250 to 500 employees. From 500 to 1,000 employees, personnel problems assume greater proportions and make desirable the employment of a personnel officer. The large industrial unit, and the combine in particular, employing more than a thousand persons, has a wide variety of personnel problems which call for degrees of specialization among members of its personnel department. In those companies, whether medium-sized or large-scale, where personnel management is an accepted practice, there is general recognition that the functions of the personnel department can be grouped into the six divisions already mentioned.

Personnel policies in industrial organizations are the concern of directors or principals. It then becomes the responsibility of management to see that policies are translated into good management practices so that the spirit and intention of policy are faithfully carried out. The personnel department, where it exists in an organization, is a specialist department used for helping the directors in their policy-making and assisting management in carrying out what has been agreed.

Personnel management in Great Britain has evolved from a 'welfare' origin. In its earliest days it may have meant little more than the good intentions of an owner who put what he felt into practice by occasional acts of benevolence or generosity. Welfare officers were first employed in a few of these 'enlightened' companies until the problems of the First World War brought about a considerable increase of similar appointments. A majority of these war-time appointments were terminated with the return of peace-time competition.

It was not until the middle thirties, following upon the serious employment and social problems which followed in the wake of periods of slump and depression, that the establishment of an employment and welfare department began to interest an increasing number of managements. Progress was relatively slow since, for economic and other reasons, the majority of employers were reluctant to regard the labour problems of management as worthy of special study and attention. Personnel management grew principally in the new industries where employers were keen to attract and maintain a stable and efficient working force, as well as in the old-established companies where employers brought a human outlook to bear on matters affecting their employees.

As a result, personnel management had won a firm place in the management organization of a number of industries before the Second World War and, during the War, as the human problems of management again assumed immense proportions, the number of personnel departments increased more than four-fold. Since the War this growth has been maintained.

The problems which confront personnel managers to-day are the improvement of factory relations to the point where national aims and the common interest of management and men may be realized, provision of the right climate of incentive for harder and better work, and making the best use of individual, or group, ability. The techniques employed by personnel managers in tackling these problems are elaborated by Mr. Moxon. Yet though these techniques are the methods by which industry seeks to promote more fairness and justice in factory life and to secure more efficient production, the will to do these things, the good intentions or principles, are as fundamental and as important as they were to the early pioneers. What makes the task more formidable is the knowledge that better management practice of to-day requires a full understanding and a greater measure of support from workpeople and their union representatives, the majority of whom have long memories and are not yet convinced that job security ultimately depends on taking every opportunity to increase production, improve quality and reduce costs.

Other topics considered by Mr. Moxon in this thoughtful and carefully ordered broadsheet are the relation of the personnel to other factory departments and the way in which a personnel department might be organized.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications

Resistant Peripheral Membranes of the Keratin Fibres

In a number of communications, Alexander and Earland[1-3] have claimed to have isolated from wool a new morphological component, a highly resistant continuous membrane lying between the usually recognized cortex and cuticle. In collaboration with Happey[4], they have further claimed to have demonstrated that the new component is a β-type protein, that is, allied in molecular structure to stretched hair, silk, etc., and that this β-type molecular structure accounts for the stability and resistance of the membrane.

The existence of a subcuticular membrane in animal hairs was suggested by the German workers Lehmann[5,6] and Elöd and Zahn[7] several years ago. Their evidence for a subcuticular origin for the tubular residues has already been criticized and the tubes shown to be derived from the *external* layers of the scaly cuticle, that is, to be cuticular sheaths[8]. To cite merely one convincing experiment: tubes were prepared from fibres which had previously been coated superficially with a thin metal layer by evaporation *in vacuo*. The isolated tubes were found to bear the metal layer which unambiguously labelled the outside surface of the cuticle[8]. Alexander and Earland have merely provided further evidence for a general rule that when the keratin fibres are brought into solution a resistant residue remains which consists of the tubular membranes enclosing a variable quantity of fibrillar cortical fragments[10].

The reason for the separation of the tubes as coherent forms is found by electron microscopy, which shows that the walls of the tubes consist of a very thin, extremely resistant membrane reinforced to a variable degree by the adhesion of granular protein[9,11]. This thin resistant membrane can be separated in a purer condition by chlorinating wool, when the membrane is inflated as small bubbles (Allwörden sacs) and can be rubbed off in fragments by shaking in water[9,12]. This latter experiment is evidence of the external location of the new membrane, which is seen to form an epicuticle, a thin layer uniformly enveloping the fibre much as if it had been lacquered. This epicuticle is indeed a new morphological component and may be a further example of the peculiarly resistant membranes which electron microscopy has revealed in animal tissues. The epicuticle of hair appears to be chemically the most resistant component of the fibre and remains when the keratin proper is dissolved. Since a certain amount of the rest of the cuticle always adheres to it, we have the possibility of forming more robust sheaths or external casts of the scaly layer, and it is these which mistakenly have been thought to come from beneath the scales.

Some preparations of these sheaths give X-ray patterns of diffuse haloes with β-type characteristics as Happey and others have noted, but one is certainly not justified in concluding from this that the tubes are a β-protein and that wool is molecularly a polyphase structure. No β-reflexions in original wool were noted by Astbury and Woods[13], although a β-protein, had it been present to the extent of 7–10 per cent, would have been detected. It is wel known[12], however, that after certain chemical treat ments causing fibre contraction, a β-structure doe develop due to modifications in the cortex of th fibre[14]. An electron microscopic examination of th residue prepared by the method of Alexander an Earland shows, in fact, a considerable quantity c cortical material, which after the chemical treatmen it has suffered may be expected to give a β-pattern In the absence of cortical impurity the tubes giv only a most diffuse X-ray pattern from which littl can be deduced.

In view of the above criticisms, it may seem un necessary to comment on the final speculation tha the β-structure is the reason for the insolubility of th tubes. Bamford, Hanby and Happey[15] have ad vanced the hypothesis that the β-structure of certai synthetic polypeptides is the cause of the insolu bility of these compounds. There is, however, a con siderable difference between synthetic polypeptide and natural proteins, and it is surely better t consider the solubility of actual proteins havin a β-structure. We find, in fact, that these are mor easily brought into solution than wool keratin; fo example, silk in acid or cuprammonium solutio and feather in reducing solutions. The suggeste explanation is not, therefore, acceptable.

The histological structure of the tubes (epicuticl plus cuticular remnant) shows that the real reason fo the separation of the tubes as coherent forms is th insolubility of the epicuticular fraction. The com position of the epicuticle is thus the main problem and the great difficulty here is to separate it in a pur form and in quantity sufficient for analysis.

[15] Bamford, Hanby and Happey, *Nature*, 166, 829 (1950).

The purpose of Dr. Mercer's communication seem to be to establish the following points: (*a*) that th material isolated by Alexander and Earland is no a subcuticular membrane; (*b*) that the β-protei contained in their material is not present in th initial fibre; and (*c*) that the insolubility of thei membranes is not connected with the β-structure.

As regards (*a*) we have no special comment although we feel that Mercer's view is probabl correct. On the other hand, Mercer's argument against the presence of 7–10 per cent of β-kerat in wool are far from convincing. It is by no mean certain that this amount of (partially disoriented β-keratin, even if it were crystalline, would be de tected by X-ray analysis. In fact, Ambrose an

Elliott[1] have shown that in the keratin of elephant hair there is about 10 per cent of the β-form; this s not visible on an X-ray photograph. On point (c), we believe that Mercer's views are unsound. While it is true that the β-protein silk may be more easily dissolved than wool keratin, this difference is not connected with the backbone configuration of the proteins, but results from the presence of cystine cross-links in the wool. Once these are broken, the resulting material dissolves readily in faintly alkaline solutions, for example, very dilute ammonia. Further, in converting the soluble α-keratin to the β-form, there is a marked decrease in solubility. Finally, ecent investigations[2] have shown that the α-form of silk fibroin is readily soluble in water whereas the β-form is insoluble.

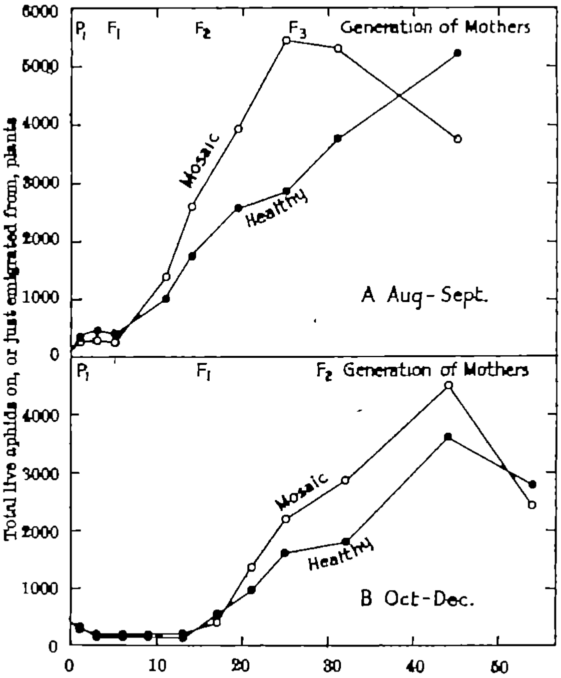
Benefits to Aphids from Feeding on Galled and Virus-infected Leaves

IT has been shown that robust green leaves which have ceased growth and not yet entered upon senescence are unsuitable, by comparison with growing or enescing leaves, for colonization by *Aphis fabae* Scopoli and *Myzus persicae* (Sulzer)[1–3]. Abnormally xtended growth or premature senescence-like hanges, or both, are characteristic of both the pseudo-galls' (curling and pocketing of leaves) and the virus diseases which plants can develop as a result of aphid attack. Experiments were therefore ndertaken to see whether such pathological changes in the plants might not be beneficial to the aphids nitiating them.

The yellow-red pocket galls formed by *Cryptomyzus ibis* on red currant leaves were tried first because the galled parts remain soft enough for the pockets o be pushed inside out, thus turning what were the est sheltered into the most exposed parts of the eaf surface. The aphids, which before were mostly nside the shelter of the pockets, were now all removed from the leaves. The leaves were washed, and resh aphids released on their morphologically upper urfaces. The majority of the aphids settled down o feed again on the galled parts of the morphologically lower surface, although these parts were now convex instead of concave, and were often facing upwards instead of downwards owing to the deformaion caused by everting the galls. The aphids' other references—for shade from the light, and for a ertical or upside-down posture—could still be deected by comparing their densities on otherwise milar leaf areas. But their preferences for the orphologically lower surface and especially for the galled parts of the leaves were more powerful. When the galls are in their normal uneverted state, the shade and posture preferences will, of course, help o get the aphids into the pockets; but they are vidently of subsidiary importance. Cage experiments confirmed that the aphids multiplied faster where they preferred to feed. So it seems that even uch simple 'pseudo-galls' can be physiologically beneficial to the insects causing them, which will be a factor in the evolution of both.



Development of *Aphis fabae* populations on sugar beets with, and without, mosaic virus disease. *A*, five plants of each kind, mosaics inoculated eighteen days before aphids put on; *B*, four plants of each kind, mosaics inoculated twelve days before aphids put on

The effect on *Aphis fabae* of feeding on sugar beets with the mosaic disease caused by a virus this aphid transmits was recorded both in free infestations developing on whole plants for several weeks, and in small cages on individual leaves for 1–4 days. The population on diseased whole plants grew distinctly faster than on healthy plants in both experiments (see accompanying graphs). As a result, overcrowding and emigration also began sooner in the former population. Given fresh plants available for the emigrants to colonize and infect, however, the rising part of the curves should be repeated, and the beneficial effect of the disease should continue exponentially. The confirmatory experiments on individual leaves involved, in all, four batches of diseased plants, some seven thousand adult apterous viviparous aphids caged in groups of ten or twenty, and some twenty-five thousand of their offspring. The average output of young per mother caged on leaves showing mosaic symptoms (systemically infected, following sap-inoculation of the plants 11–240 days before the experiment) was compared with the concurrent output of young on leaves of similar age on uninfected plants of the same batch. The output was higher on the mosaic than on the healthy leaves in twelve out of thirteen experiments on growing leaves, in eight out of nine experiments on mature leaves and in three out of three experiments on senescing leaves. The ratios between the two outputs, mosaic/healthy, from all twenty-five experiments, gave a mean of 1·41 with a standard error of 0·062. Evidently the disease renders the whole plant, and not merely the mature leaves, more suitable for this vector. The epidemiological and evolutionary consequences, for both virus and vector, invite further attention; so also, from the point of view of plant physiology, does the fact that growing, senescing, galled and mosaic-diseased leaves all have something in common for the aphids.

My thanks are due to Dr. K. M. Smith for carrying out the virus inoculations.

A New Type of Pathogenic *Mycobacterium*

IN 1948 skin lesions due to a new acid-fast organism, *Mycobacterium ulcerans*, were reported from Australia[1]. The lesions were swarming with bacilli; but no growth was obtained on media incubated at 37° C. Culture at 33° C. gave growth.

Some seventy cases of a rather chronic, papulous, cutaneous disease producing ulcerations, which may be due to another acid-fast organism likewise not growing at 37° but at 31° C., have been observed in the past few years at Örebro, Sweden. The lesions were usually localized to the elbows. Some of the patients reported that they had scratched the elbow in a swimming pool two to three weeks earlier. The disease always healed within six months to two years, even when left untreated.

We examined histologically the lesions from thirty patients with this disease. Tuberculoid granulation tissue was almost always found. In one case a few acid-fast organisms were observed inside the lesion. Lesions from twenty patients were examined bacteriologically. In three cases acid-fast organisms growing at 31° C. were isolated. Large yellowish-white colonies appeared on Lœwenstein medium. The colonies were flat with a central nipple. The growth obtained when the glycerine concentration was 0·5–10·0 per cent was good, but when glycerine was omitted from the medium it was poor. Incubation at 31° C. gave growth after 8–10 days; at 22° C. growth usually required three weeks. Culture at 37° C., even with prolonged incubation, gave no growth. The bacilli were Gram-positive and strongly acid-fast. They were not sensitive to *para*-aminosalicyclic acid in experiments kindly carried out by Prof. J. Lehmann (Gothenburg).

Material was then collected from the swimming pool and examined. Organisms with the same characteristics as the bacilli isolated from the three human cases were found in scrapings from the cemented wall of the pool and in samples of the water.

The pathogenic properties of the acid-fast bacilli isolated were studied experimentally in animals. The organisms were found to be only slightly pathogenic for guinea pigs; large intraperitoneal injections occasionally gave localized abscesses in the scrotum. Papulous lesions showing the same microscopic changes as the human lesions were reproduced in the skin of rabbits by infecting ulcerations, produced by rubbing the shaved skin with sandpaper, with a suspension of organisms. Following intraperitoneal, and sometimes also intravenous, injections of bacilli into male rabbits, granulomatous inflammation with caseous necrosis was found in the scrotum. The lesions contained a few acid-fast organisms.

Most white mice infected intraperitoneally became seriously ill and died. Abscesses and ulcerations appeared on the tail, the paws and the scrotum. Widespread lesions were frequently found in the internal organs, especially in the lungs, which showed numerous caseous patches. The lesions produced in the mice contained enormous masses of acid-fast bacilli. Amyloidosis of the liver, spleen and kidneys was frequently observed. After several months of illness a few of the mice seemed to show signs of recovery.

Rats infected intraperitoneally showed no signs of disease; but on microscopic examination numerous tuberculoid structures were found in the omentum and sometimes in the hilar lymph nodes. The lesions contained many acid-fast bacilli. Intravenous or intraperitoneal injection of the bacilli into chickens produced no lesions. The effect of such injections on other animals is being studied.

Guinea pigs and rabbits infected by intraperitoneal injection were tested intradermally with tuberculin (Tuberculin P.P.D. kindly supplied by Dr. K. Tolderlund, of the State Serum Institute, Copenhagen). No reactions to a dose of 5,000 tuberculin units were observed in guinea pigs followed up for three months. Some rabbits gave definite reactions to a dose of 500 tuberculin units six to seven weeks after the injection of the bacilli.

A suspension of autoclaved bacilli was injected intradermally into three tuberculin-positive human volunteers. After forty-eight hours, there appeared skin reactions similar to those obtainable with tuberculin. Later, these lesions became necrotic. Microscopic examination showed the presence of tuberculoid granulations.

Judging by the behaviour of the bacillus, it seems to be a hitherto undescribed type of pathogenic *Mycobacterium*. It is probably not identical with *Mycobacterium ulcerans*. Dr. G. Buckle (Australia) was kind enough to place at our disposal cultures of *Mycobacterium ulcerans*. The bacteria under discussion were found to differ from the Australian bacilli as regards both growth on artificial media and their effect on experimental animals.

Cases of tuberculoid skin granuloma caused by atypical acid-fast bacilli have been reported from Sweden[2,3]. The histological picture resembled that of the lesions seen in our patients. In the less advanced cases, however, numerous rather thick, acid-fast bacilli were seen in the lesions. Culture at 37°, 31° and 24° C. showed no growth[4]. This may therefore be a disease differing from the one observed by us. Tuberculoid skin-granuloma after swimming-pool accidents have been reported elsewhere[5,6], and it is possible that further investigations will show that such skin lesions are also due to acid-fast organisms similar to those described above.

Surgically induced Splenogenic Anæmia in the Rabbit

THAT alterations in the functional interrelationships of the liver and spleen may cause changes in the formed elements of the blood is suggested by the syndrome of portal vein hypertension. In this connexion, the experimental work of Bock and Frenzel[1] is noteworthy. These workers reported that ligation of the splenic and gastric coronary veins leads to anæmia and leukopænia in the rabbit.

The present study, involving about thirty rabbits, is an examination of the pathogenesis of this anæmia. In a group of eight rabbits, a mean fall of 26 per cent in the red cell count was observed following the ligation of the splenic and gastric coronary veins. Similar changes in hæmoglobin and hæmatocrit were observed. This anæmia is well established by the fourth or fifth day after operation and persists for four to six weeks, after which the red blood cell count returns to normal. Leukopænia, as reported by Bock and Frenzel[1], was not seen in the present work. Splenectomy, as is to be expected from other reports[2], nduced no such anæmia.

Our experimental evidence indicates that: (1) the spleen can elaborate an anæmia-producing factor; (2) this factor is normally inactivated by passage hrough the portal venous system; and (3) when he splenic venous blood is diverted directly into he caval system by-passing the liver, anæmia results.

That splenic congestion plays no significant part in the anæmia is indicated by several findings: (a) the anæmia never reaches maximal intensity beore the fourth day, by which time the collateral irculation is well established; (b) gross increase in pleen size is never noted beyond the first few hours after ligation; and (c) ligation of the splenic and gastric coronary veins after intravenous injection of red cells labelled with phosphorus-32 shows that ess than 4 per cent of the circulating red cells are in the spleen eighteen hours after ligation.

Devitalization of splenic tissue by congestive schæmia (in the first few hours after operation) and absorption of such necrotic tissue apparently play no significant part. Free introduction of the completely extirpated spleen into the peritoneal cavity causes no anæmia, although the spleen is completely absorbed; moreover, absorption of devitalized spleen would not be expected to continue for the six-week duration of the anæmia.

There remains the possibility that the spleen can elaborate a factor which is capable of producing anæmia when introduced into the general circulation without first passing through the portal system. Data which are compatible with this concept include: (a) splenectomy at the height of the anæmia leads to prompt return to normal of the red cell count; (b) intramuscular injections of pestle-homogenized whole normal spleen induce comparable anæmia in he splenectomized animal (this has not yet been ried with the intact animal); (c) *in vitro* incubations f red cells of normal and vein-ligated animals in he plasma of the vein-ligated animal cause significant hæmolysis; (d) upon recovery of the animal from he induced anæmia, injection of the portal system with liquid latex shows newly formed and opened hannels which convey significant amounts of splenic enous blood to the portal system. After recovery from the anæmia, the red cell count can again be epressed by ligation of the short gastric vessels.

This splenogenic anæmia was further characterized by studies of hæmoglobin metabolism using alpha-carbon-14-acetate as hæmoglobin precursor.

The carbon-14 activity of the circulating-erythrocyte-hæmoglobin in the vein-ligated animal does not exhibit the normally observed plateau of about sixty days[3] after the injection of the labelled precursor. Rather, it shows a random decay curve indicative of a hæmolytic type of anæmia[4]. The estimated life-span of the red cell in the vein-ligated animal is of the order of 15–25 days, as contrasted with the normal life-span of 65–70 days.

Psychological and Biochemical Effects of Lysergic Acid Diethylamide

Stoll[1] and Condrau[2] have shown that the psychological effects of lysergic acid diethylamide ($LSD-25$), an amide of one of the constituents of ergot, are similar to those obtained in mescaline intoxication, but are produced by the oral administration of quantities as small as 0·02–0·06 mgm. While, in our experiments, the symptoms varied greatly from one person to another, the basic pattern of reaction seemed the same in twenty subjects who were members of the hospital staff. After initial slight autonomic symptoms, such as enlarged pupils, feeling of cold, 'goose flesh' and mild nausea, the most marked changes were emotional, a pleasurable feeling tone amounting to euphoria and bursts of laughter; this sometimes alternated with, or later was followed by, depression. There was also a general complaint of a feeling of lassitude and muscular weakness. In spite of some difficulty in concentrating, consciousness remained clear and introspection almost undisturbed. Visual illusions and hallucinations, especially illusions of movement, colour and distortions of the body image were frequently present.

The minute dosage required to produce the psychological effect of lysergic acid diethylamide suggested that its mode of action was due to an anti-enzyme action. Since, normally, the only substrate metabolized by the brain cell is glucose, an investigation of the effect of the drug on carbohydrate metabolism *in vivo* was attempted.

Blood samples were taken from the fasting subjects and at intervals of one and two hours after the administration of the drug, the following analyses being made by the methods indicated: glucose[3], hexosemonophosphate[4], lactic acid[5], alkali reserve[6], pyruvic acid[7], inorganic phosphate, total acid-soluble phosphate, lipoid phosphate and adenosine triphosphate[8]. On a subsequent day, identical control analyses were made on most of the subjects, but with the substitution of a placebo for the drug.

No significant variations in the result of the two sets of analyses were found, except in the cases of glucose and hexosemonophosphate. For the latter the mean level of the experimental analyses rose by 1·65 mgm./100 ml. one hour after taking the drug and fell by 0·9 mgm./100 ml. during the subsequent hour. The corresponding figures for the control analyses were falls of 2·3 and 2·4 mgm./100 ml. respectively. In the case of blood glucose the experimental results showed a mean rise of 15 mgm./100 ml. after one hour and 11 mgm./100 ml. after two hours. The control analyses showed a mean fall of 1 mgm./100 ml. after one hour and a mean rise of 1 mgm./100 ml. after two hours.

The subjects were fasting and at rest throughout both the experimental and control periods. In these circumstances the only available source of carbohydrate would be glycogen, the first step in the metabolism of which is the formation of hexosemonophosphate. Under conditions of complete rest the rate of glycogen metabolism might be expected to fall, and this was reflected by a fall in the blood concentration of hexosemonophosphate in the control analyses. The increases in hexosemonophosphate and glucose in the experimental observations suggest that there is an increased metabolism of glycogen coupled with a probable block in the breakdown of hexosemonophosphate. If the increase of hexosemonophosphate should be due to increased demand for carbohydrate by the central nervous system, one would expect increases also in lactate, pyruvate, etc., together with a decrease in glucose. The fact that, on the contrary, no such changes occurred and the glucose is raised, suggests that the raised level of hexosemonophosphate is caused by a break of the cycle at this point.

A certain hypobulia and absorption in the passive state of feeling made the relation in time of biochemical to psychological change somewhat imprecise. However, symptoms of the vegetative system and of emotional nature appeared during the first hour and before the more specific symptoms such as illusions, hallucinations and other disorders of the perceptive field, which were of longer duration.

It is suggested that the changes in carbohydrate metabolism observed after the intake of lysergic acid diethylamide are responsible for at least part of the psychological symptoms. The alternative view that the alterations in carbohydrate metabolism are a parallel effect of the drug unconnected with its psychological effect seems improbable. Further studies which are now in progress should elucidate this point.

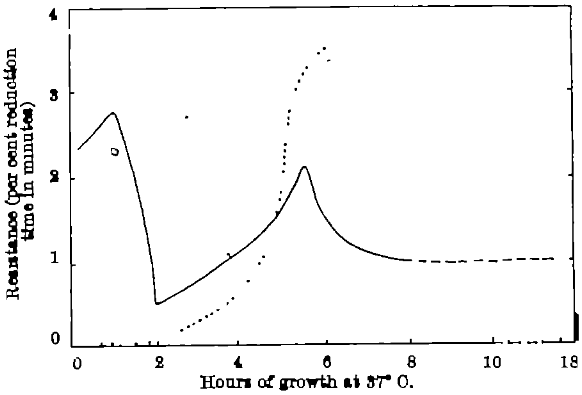
Variation with Age in the Resistance of Bacterial Cells

IN an article in *Nature* of April 28, p. 666, Sir Cyril Hinshelwood discusses some of the possible explanations for deviations from the logarithmic order of death sometimes shown among bacteria exposed to disinfecting agents. Where the final stages of decline are abnormally protracted (that is, where there is a resistant 'tail' of organisms), he suggests that the most obvious explanation would be the presence of some cells of abnormally high resistance, and that these might originate from the interruption of growth at the appropriate stage in the cell-cycle. He considers it possible that at certain phases in the growth of each individual cell there might be a stage of maximum resistance, possibly when the internal condition of the vegetative cell bears the maximum resemblance to a spore.

The work of Ellicker and Frazier[1] with *Bacterium coli* cultures exposed to heat at various ages lends support to this view. These workers found that, after falling to a minimum during the period of most active reproduction, the resistance of their organism reached a high level as the culture entered the stationary-growth phase.

Recent work carried out in this laboratory on the thermal resistance of some strains of *Streptococcus faecalis* has yielded very similar results, and it is hoped to publish these in more detail elsewhere. It was found that after exhibiting very high resistance during the lag phase of growth, the young cultures then experienced a period of minimum resistance which later gave place to a second peak as the rapid growth phase neared its end. Later still, the resistance fell to a level characteristic of mature cultures (see graph).



Variation with age in the thermal resistance of one strain of *Str. faecalis*. Resistance—at 60° C.—is expressed as a percentage reduction time, and the growth curve is obtained by direct microscopic counts of one loopful of incubating culture

The time taken for the full growth/resistance cycle to be accomplished varied with different strains of the same organism; but the general shape of the curve remained the same. Change in incubation temperature did not affect the general character of the age/resistance relationship; but, apart from the obvious effect on the time taken to pass through each stage (varying with the growth-rate), it did influence the degree of resistance attained at any one stage.

The death-rate of young cultures in the logarithmic growth-phase, plotted as the logarithm of the number of surviving cells against time, was characteristic and was rarely in the form of a straight line. Many of the graphs were curves showing a preliminary 'rush' in death-rate, probably due to the large proportion of cells in the most susceptible stage of their cycle (that is, those actively engaged in multiplication). A resistant 'tail' of cells dying more slowly was most distinct in these cases—these were probably the older, more mature cells, which must gradually accumulate in number as reproduction slows down, thus causing the high resistance typical of cultures nearing the maximum-growth stage.

The death-rate of young cultures still in the lag-phase of growth and also of the older ones nearing the stationary phase approached more nearly a logarithmic straight line, in the same way as those of mature cultures.

From this experimental work, it was concluded that one of the possible causes of any variations in resistance among cells in mature cultures might be the slight variations in true (physiological) ages of the cells comprising such cultures. The cells in a 24-hr. culture would be mostly very similar in age; but if some growth were proceeding, however slowly, this might be just sufficient to produce variations in resistance, quite apart from any gradations found in a homogeneous culture. This conclusion is somewhat similar to those drawn by Sir Cyril Hinshelwood.

Active Relaxation of Unstriated Muscle produced by Adrenaline

ADRENALINE is one of the most powerful inhibitors of tone in unstriated muscle; it is therefore expected to produce active relaxation. Active relaxation by adrenaline has been found in pieces of circular muscle of frog's stomach[1,2] and in guinea pig's uterus[3]. The movements of unstriated muscle, compared with those of striated muscle, are very sluggish, so that complicated apparatus is not necessary to follow conraction and relaxation. These experiments with adrenaline and frog's stomach muscle are most satisfactory, as there is no preliminary contraction except hat of the normal tone, and the muscle just lengthens.

Transverse and longitudinal pieces from the stomach muscle of the frog *Rana tigrina* were used[4]. The length of the unloaded muscle was measured n saline of *p*H 8 before and 20 min. after adding adrenaline chloride. The experiments were performed at 25–27·5° C., this being the optimum temperature or active relaxation. On addition of adrenaline, ircular muscle of frog's stomach begins to lengthen almost immediately up to a maximum of 40 per cent of its initial length, the lengthening being almost omplete in about ten minutes. The muscle relaxed actively in all concentrations of adrenaline tested, the experimental range being 1 in 10 million to 1 in 10,000, and the maximum relaxation occurring in in a million upwards. Compared with circular fibres, ongitudinal fibres lengthened very little. Thus in wenty experiments, ten showed no change in ength, while the rest lengthened by 4–9 per cent. The reaction of the longitudinal fibres was examined o exclude lengthening of circular fibres by their ontraction if there were any such effect. Near the cardio-œsophageal sphincter, the longitudinal bres relax more (5–25 per cent in eight experiments), o that here both sets of fibres relax actively. Circular muscle from the cardiac half of the stomach also is more sensitive than that from the pyloric half, in which active relaxation may not occur owing to the presence of alactic tone[5].

Active relaxation in frog's stomach muscle undergoes seasonal variations; it is best observed when the room temperature is 25–30° C. During the winter months, it diminishes or is absent, even if the temperature of the saline is raised to 25–30°. The optimum *p*H is 8; but if the tone is great, increase in acidity to *p*H 6·5 may indirectly improve the response by diminishing tone[1]. Substances that increase tone, such as replacement of the chloride of the saline with bromide, iodide, thiocyanate, or excess of potassium ions, antagonize active relaxation. Cyanide abolishes active relaxation, which is restored by glucose.

The virgin guinea pig's uterus or a small portion of uterus in early pregnancy has been used to demonstrate active relaxation produced by adrenaline. The guinea pig is killed by a blow on the head, the uterus is removed and the uterine horns are immersed in saline of *p*H 8 at 25–30° C.[6,7]. The horns are then split longitudinally and if pregnant the contents are removed. The muscles begin to relax actively immediately on addition of adrenaline. The maximum relaxation, up to about 60 per cent of its initial length, is produced by small concentrations (1 in 10 to 1 in 5 million). It becomes less with larger concentrations[3], owing to the tendency to contraction with such doses. It is well known that small concentrations of adrenaline produce inhibition although large doses produce contraction. With large doses, after 10 min. the muscle begins to contract, and as tone thereafter increases, active relaxation becomes less or disappears if the experiment is repeated every 30 min. With small concentrations, the experiment can be repeated, as there is no tendency to contraction or such increase of tone. The elongation is not due to contraction of the circular fibres, as there is no eversion of the split longitudinal edges; moreover, substances that cause contraction do not produce any elongation. Active relaxation may be produced by concentrations of adrenaline as low as 1 in 1,000 million. The optimum temperature is 25–30° C. At 37° C., active relaxation is feeble and, if tone increases, it is absent. Substances that increase tone, such as lithium, ammonium, potassium, excess of calcium, strontium, barium, bromide, iodide, nitrate or thiocyanate ions, diminish or abolish active relaxation. Cyanide abolishes active relaxation, which may partially be restored by glucose. Longitudinal muscle of rabbit's gut, though very sensitive to adrenaline as regards passive relaxation, does not relax actively. Therefore the tonus of unstriated muscle can be of three kinds, when active or passive relaxation by adrenaline is considered: (1) the muscle does not relax actively or passively; (2) the muscle relaxes actively as well as passively; (3) the muscle relaxes passively but not actively.

Active relaxation due to the action of adrenaline on the contractile mechanism should be tested on a background of mild contraction, such as produced by *p*H 6·5 (phosphate)[8]; there are individual and seasonal variations, some muscles not contracting in phosphate. Similarly, the action of acetylcholine on the contractile mechanism should be tested on a background of relaxation, such as is produced by potassium[8].

A convincing example of active relaxation has been found to occur in the retractors of the introvert of the marine worm *Golfingia* (*Phascolopsis*) *gouldii* (Pourtales). The retractors are removed along with the brain and immersed unloaded in sea water in a Petri dish. The brain is stimulated by slight pressure with a forceps. The muscles contract and relax actively again. In more than 20 muscles, the relaxation was from 100 to 200 per cent of their length during the contracted state. If sodium cyanide (1 in 10,000) is added to the sea water, the muscles contract, but do not relax actively. Microscopic examination shows that the muscle consists of longitudinal bundles of fibres[10].
